
The tickmarks on the y-axis of the top panel of Fig. 3 should be labeled 0, 5, and 10, not 0, 10, and 20. The corrected figure is shown below. We thank W. Friedland for drawing our attention to this error.
Evidence for the Organization of Chromatin in Megabase Pair-sized Loops Arranged along a Random Walk Path in the Human G0/G1 Interphase Nucleus

Abstract. We determined the folding of chromosomes in interphase nuclei by measuring the distance between points on the same chromosome. Over 25,000 measurements were made in G0/G1 nuclei between DNA sequences separated by 0.15–190 megabase pairs (Mbp) on three human chromosomes. The DNA sequences were specifically labeled by fluorescence in situ hybridization. The relationship between mean-square interphase distance and genomic separation has two linear phases, with a transition at ~2 Mbp. This biphasic relationship indicates the existence of two organizational levels at scales >100 kbp. On one level, chromatin appears to be arranged in large loops several Mbp in size. Within each loop, chromatin is randomly folded. On the second level, specific loop-attachment sites are arranged to form a supple, backbone-like structure, which also shows characteristic random walk behavior. This random walk/giant loop model is the simplest model that fully describes the observed large-scale spatial relationships. Additional evidence for large loops comes from measurements among probes in Xq28, where interphase distance increases and then locally decreases with increasing genomic separation.

Shortly after cell division, the mitotic chromosomes decondense and diffuse into the interphase nucleus. While individual chromosomes cannot be discerned, important processes related to chromosome function take place. Regulatory factors interact with chromatin, DNA is made accessible for transcription, RNA is produced and processed, and repairs are made of DNA strand breaks. When the chromosomes reappear for the next mitosis, they have been duplicated and prepared for rapid partitioning over the daughter cells. The complexity of these processes raises many questions about the large-scale organization of chromosomes and how this organization relates to cell function (e.g., Blobel, 1985; Manuelidis and Chen, 1990; Cook, 1991; Lawrence and Singer, 1991; De Boni, 1994).

Diverse models, ranging from highly random to highly organized, have been proposed for the higher-order organization of interphase chromatin. These models variously involve irregularly folded fibers (DuPraw, 1965), radial loop structures (Manuelidis and Chen, 1990), giant loops (Ostashevsky and Lange, 1994), semirigid orientation ("Rabl" configuration) (Rabl, 1885; Comings, 1968), or random polymers confined by tethering or external forces (Hahnfeldt et al., 1993). Some models assign to chromosomal organization a dominant role in cell function. Cremer et al. (1993) suggested that gene-rich and early-replicating chromatin is systematically organized so that it is readily accessible to the transcription and replication machinery. Using elegant optical techniques, Sedat and co-workers demonstrated a systematic arrangement of Drosophila prometaphasic chromosomes, with telomeres and centromeres located at opposite nuclear poles (Hiraoka et al., 1990a). It is not clear, however, whether these observations apply to mammalian cells.

While much has been learned about chromatin structure at small scales (<100 kbp) (for reviews see van Holde, 1989; Lewin, 1994), there have been few quantitative studies on the large-scale geometry of mammalian interphase chromosomes (van den Engh et al., 1992). Consequently, it has not been possible to discriminate among the various proposals for nuclear structure.

Fluorescence in situ hybridization (FISH) offers new possibilities for bringing out structural features of chromosomes within interphase nuclei. The sites of specific DNA sequences can be fluorescently marked for direct microscopic examination. Using FISH, an important discovery about interphase chromosomes was made. Probes that stain or "paint" whole chromosomes show that individual

chromosomes occupy restricted subcompartments or domains in the mammalian interphase nucleus, rather than being dispersed throughout the nuclear volume (Lichter et al., 1988; Pinkel et al., 1988). The shape of these domains is irregular and highly variable among cells. Details about the path taken by chromatin within these domains have remained obscure. The variable character of the chromosomal domains implies that systematic patterns of chromosomal organization, if they exist, can only be derived from a statistical analysis of a large number of observations.

We have developed a statistical approach to study the large-scale geometry of individual interphase chromosomes (van den Engh et al., 1992). In this approach, the folding of chromatin is inferred from the distances measured between two probes from known genomic sites. Measurements in one cell are inconclusive, but the pattern of folding can be revealed by repeated observations of a given probe pair in many cells and by observations of many probe pairs. The relative positions of two small (~40-kbp) DNA sequences are determined in large numbers of nuclei. One probe’s site is labeled by FISH with a green fluorochrome, and the second probe’s site is labeled with a red fluorochrome. The separation, in basepairs, of these sequences along the DNA molecule is known. Sites separated by 50 bp or more are resolved in interphase nuclei by using conventional fluorescence microscopy (Trask et al., 1989a). Thus, chromatin folding at scales >50 kbp can be analyzed with this technique.

Using this approach, we showed previously that over relatively short (0.1 to ~2 Mbp) genomic separations interphase chromatin exhibits the random walk behavior typical of linear polymers (van den Engh et al., 1992). Linear polymers can be considered as long, flexible molecular chains that fold in a random manner. The statistical properties of such chains are well studied. The overall length and shape of a folded chain are accurately described by statistical methods based on random walk models (Cantor and Schimmel, 1980; Doi and Edwards, 1988; Flory, 1988). One hallmark of random walk, polymer behavior is that the mean-square projected two-dimensional distance between points on a chain in its random conformations is linearly proportional to the separation between the points on the straightened chain, d,

\[ \langle r^2 \rangle = d \]

where \( r \) represents distance between points on the randomly folded molecule, and \( \langle . . . \rangle \) indicates mean. Using a set of probes spanning a genomic range of 50 kbp-4 Mbp, we found that chromatin chains show such random walk behavior (van den Engh et al., 1992). For genomic separations <2 Mbp, mean-square interphase distance \( \langle r^2 \rangle \) increases as a linear function of genomic separation \( d \). An additional similarity between polymers and chromatin in the range of 0.1 to ~2 Mbp was also noted in repetitive measurements of distances between two given probes. The statistical distribution of such distances also conforms to the pattern expected for polymers. Thus, on the scale of 0.1-2 Mbp, chromatin structure is dominated by random influences.

An abrupt change in the polymer-like behavior of interphase chromatin was observed around 2 Mbp (Trask et al., 1991, 1993a; van den Engh et al., 1992). Above this genomic separation, mean interphase distance appeared to plateau. This plateau indicated that additional constraints are acting to prevent the random dispersion of chromatin. The short distance measurements did not allow us to draw conclusions about the nature of these constraining structures, however.

In this paper, we extend our quantitative studies on the conformation of mammalian chromosomes in interphase. We present the first data relating interphase distance to genomic separation for separations up to the length of an entire chromosome. Using probes on three different human chromosomes, interphase distances were measured for 131 genome separations ranging from 0.15 to 190 Mbp. We find that the relationship between mean-square interphase distance and genomic distance has two linear phases. These two linear phases are clear indication of two different regimes of flexible chain, polymer-like behavior. Additional evidence for random walk behavior stems from our analyses of the statistics of the distance distributions. These two polymer-like regimes can be interpreted as a systematic organization of chromatin in giant loops returning to a flexible backbone. Observation of apparent inversion in probe order in the 2- to 4-Mbp range, with mean interphase distance locally decreasing as a function of genomic separation, is provided here as further evidence of a looped chromatin structure. On the basis of these findings, we propose a random walk/giant loop model for interphase chromosomes. The mathematical details of this model, based on the data presented below, are being presented elsewhere (Sachs et al., 1995).

Materials and Methods

For most of the experiments described, human normal male fibroblast cells were grown to confluence without medium change for 2–4 d. Flow cytometric analyses show that these cultures contain >95% of cells in G0/G1. Nuclei were treated for 15 min at 37°C in 40 mM hypotonic KCl buffer, centrifuged, fixed three times in 3:1 methanol/acetic acid, and dropped on glass microscope slides. The nuclei were then denatured by dipping the slides in 70% formamide/2 × SSC at 72°C followed by dehydration in a series of cold ethanol. Nuclei were also prepared by two alternative procedures. The first was exactly as described above, except that the hypotonic step was omitted. The second procedure was developed by Popp et al. (1990) in an effort to better preserve nuclear organization on the scales we analyze here. Fibroblast cells were grown on coverslips, washed in PBS, fixed in 4% paraformaldehyde in PBS for 5 min, washed again in PBS, and incubated twice for 5 min in 0.1% Triton X-100 in PBS. The slides were then washed in 0.1 M Tris-HCl (pH 7.3) for 2 min, equilibrated in 20% glycerol in PBS for 20 min, and exposed to three freeze-thaw cycles by dipping in liquid nitrogen. The slides were stored at 4°C in PBS before use. To avoid any exposure to ethanol, the slides were placed in ice-cold 70% formamide/2 × SSC after denaturation. Slides prepared by all three procedures were hybridized to labeled DNA sequence probes in 50% formamide/10% dextran sulfate/2 × SSC at 37°C as described previously (Trask, 1991a; van den Engh et al., 1992). For each experiment, two cosmid probes, marking different chromosomal locations, were differentially labeled with biotin or digoxigenin by nick translation and hybridized simultaneously to nuclei. Probe sites were detected with different fluorochromes using avidin–Texas red and FITC-conjugated antibodies directed against digoxigenin. Nuclei were counterstained with 4',6-diamidino-2-phenylindole (DAPI) in a glycerol- and phenyldiamine-based antifade solution (Johnson and Noguera-Araujo, 1981).

The probes used in the study are illustrated in Fig. 1. 10 cosmids from within a 4-Mbp region of 4p16.3 were obtained from Marcy Macdonald (Massachusetts General Hospital, Boston, MA) and Gillian Bates (Imperial Cancer Research Foundation, London, U.K.). Cosmids representing locations within a region of ~3.5 Mbp of N028 were provided by Jane Gitschier (University of California, San Francisco), Jean-Louis Mandel (INSERM, Strasbourg, France), Anne-Marie Pousta (Deutsches Krebs-
Forschungszentrum, Heidelberg, FRG), and Kay Davies (John Radcliffe Hospital, Oxford, UK). Cosmids containing sequences hybridizing to 10, 8, and 7 different points along chromosomes 4, 5, and 19 were obtained from Rick Myers (Stanford University, Stanford, CA), Greg Landes (Integrated Genetics, Framingham, MA), and Anthony Carrano (Lawrence Livermore National Laboratory, Livermore, CA), respectively. Fibroblast nuclei are flattened ellipsoids, a feature that confines our analyses to two dimensions. Photography and distance measurements were performed in a blind fashion, without knowledge of the genomic separation of the hybridized probes. For each probe pair, photographs were taken of randomly selected nuclei (640T film; Scotch 3M, St. Paul, MN, exposure ~20s) using an Axiopt microscope (Carl Zeiss, Inc., Thornwood, NY) equipped with a x100, 1.3 NA plan-Neofluar objective and a band pass filter (ChromaTechnology, Brattleboro, VT) selected to transmit Texas Red, FITC, and a slight amount of DAPI counterstain. Photographic images were projected at a magnification of ~10,000 onto a digitizing board (40 lines/mm; Summagraphics Corp., Seymour, CT). The coordinates of paired red and green hybridization were entered through the digitizing board into a computer (NEXT Computer, Inc., Palo Alto, CA) for further analysis (van den Engh et al., 1992). An average of 179 (range, 50-361) point-to-point distances was measured for each probe pair. Digital image collection was contemplated, but deemed too slow and costly for the large number of distance measurements (~25,000) and images (~4,000) needed for this study.

To assess overall nuclear morphology, the DAPI staining patterns of alternatively fixed nuclei, before and after denaturation and FISH, were compared with nuclei in unfixed cells (slightly permeabilized to DAPI with 0.02% Triton X-100) using conventional epifluorescence microscopy as well as a DeltaVision microscope and three-dimensional image processing system (Applied Precision Inc., Mercer Island, WA). Preparations were stained with 0.1 μM DAPI in antifade for 2 h. The DeltaVision system collects high resolution images (pixels 0.045-0.076 μm on a side) separated by 0.2 μm in the z-dimension and corrects these optical sections for out-of-focus information by using a deconvolution algorithm (Agard et al., 1989; Hiraksa et al., 1990b).

Results

The Relationship of Mean-Square Interphase Distance and Genomic Separation Has Two Linear Phases

Interphase distance was measured among 19 probes distributed along chromosome 4 (Fig. 1). Fig. 2 shows mean-square interphase distance, \( \langle r^2 \rangle \), and genomic separation for 80 probe pairs representing genomic separations ranging from 0.13 to ~10 Mbp. We here plot \( \langle r^2 \rangle \), rather than mean interphase distance \( r \) or its square \( \langle r^2 \rangle \), to facilitate comparison of our data to the predictions of polymer models (e.g., Cantor and Schimmel, 1980; Sachs et al., 1995).

The observed relationship for genomic separations >10 Mbp has several notable features. (a) \( \langle r^2 \rangle \) increases linearly with genomic separation. (b) The slope of the relationship is significantly positive (0.08 μm²/Mbp). (c) The best-fit linear regression line intersects the y-axis at \( \sim 2.5 \) μm². (d) The spread of the data points around the regression line is roughly constant across the entire genomic separation range (\( \sim 1.5 \) μm²).

The slope of data points for genomic separations <4 Mbp differs markedly from the slope observed for probes >10 Mbp apart. The short distance measurements confirm our earlier findings on different nuclear preparations (van den Engh et al., 1992) and allow additional features to be seen. (a) Genomic separation in the range from 0.1 to \( \sim 1.5 \) Mbp is correlated linearly to \( \langle r^2 \rangle \) (Fig. 2 B). (b) The y-intercept of this relationship is approximately zero. (c) The slope of the relationship through points <2 Mbp is 1.9 μm²/Mbp. This slope is ~20-fold greater than the slope of the relationship through the points for genomic separations >10 Mbp (Fig. 2 A). (d) A marked decrease in slope is observed near 2 Mbp.

A Biphasic Relationship Is Also Observed in Alternatively Prepared Nuclei

The measurements shown in Fig. 2 were obtained on nuclei exposed to a hypotonic buffer, methanol/acetid acid fixative, and ethanol before FISH (hypo-MAA). Two experiments were performed to determine whether these pretreatments affect the spatial relationships among sequences in interphase chromosomes. In the first experiment, eight probe pairs, representing genomic separations ranging from 0.25 to 190 Mbp, were evaluated in nuclei that were not exposed to hypotonic buffer (data not available).
Figure 2. The relationship between the mean-square interphase distance, $<r^2>$, and genomic separation, $d$, for probes on chromosome 4. A total of 36 probe pairs in the 10–190 Mbp range (black symbols) and 44 probe pairs in the 0.1–4 Mbp range (white symbols) was analyzed using hypotonically swollen and methanol/acid fixed G0/G1 fibroblast nuclei (preparation 384). A shows the entire distance range; B shows an expanded view of values <4 Mbp. Each data point represents an average of 154 interphase distance measurements (range: 90–249). SEMs are not shown, but are ~4% of the mean. See legend to Fig. 1 for estimates of error in genomic separation values. Solid line is the best-fit linear regression line through the data points >10 Mbp. Dashed line is the best-fit linear regression line through the data points <1.5 Mbp. These two lines are shown for reference on both A and B. The two broken (dash-dot) lines refer to a random walk/giant loop model for interphase chromosome geometry (see Discussion and Sachs et al., 1995). According to the model there should be a “cloud” of points between the two broken lines.

shown). In the second experiment, 10 probe pairs, representing genomic separations from 0.15 to 190 Mbp were evaluated in nuclei of cells grown on coverslips, fixed in situ with paraformaldehyde, permeabilized with Triton X-100, and subjected to three freeze-thaw cycles (Fig. 3). These nuclei were not exposed to methanol, ethanol, acid, or hypotonic swelling. Nuclear dimensions of paraformaldehyde nuclei were ~0.75 times shorter than those of hypo-MAA nuclei. The pattern of staining with DAPI, a DNA-specific fluorochrome, of paraformaldehyde-fixed nuclei is indistinguishable from that of unfixed nuclei and, after summation of optical sections to simulate physical projection, similar to hypo-MAA nuclei (not shown). Denaturation and FISH caused no noticeable changes in the DAPI staining pattern of the three preparations (not shown). Absolute mean distances were smaller in these two alternative nuclear preparations (~0.8- and ~0.7-fold), but relative probe-to-probe distances were similar to those observed in hypo-MAA nuclei. A marked biphasic relationship between mean-square interphase distance and genomic separation was observed regardless of preparation procedure (Fig. 3).

Measurements on Chromosomes 5 and 19 Confirm the Long Distance Observations on Chromosome 4

A linear relationship between $<r^2>$ and genomic separation, with a nonzero y-intercept, was also observed using probes distributed on chromosome 5 and chromosome 19 (8 and 7 probes, respectively) (Fig. 4). Using 42 probe combinations, the interphase proximity was determined of sequences separated by 15–180 Mbp on chromosome 5, and by 6–50 Mbp on chromosome 19. The slopes of the re-
Figure 4. The relationship between mean-square interphase distance, \( \langle r^2 \rangle \), and genomic separation, \( d \), determined for human chromosomes 5 (solid circles) and 19 (open circles). A total of 25 probe pairs for chromosome 5 and 17 probe pairs for chromosome 19 was analyzed using nuclear preparation 384. Each data point represents an average of 165 interphase distance measurements (range: 50–226). Errors are not shown, but are as described in legend to Fig. 2. The solid lines are the best-fit linear regression lines through the data points on chromosomes 5 and 19, and the dotted line is the best-fit linear regression through the data points >10 Mbp on chromosome 4 (from Fig. 2).

Figure 5. Comparisons of interphase distance distributions and the Rayleigh distribution. (A) Theoretical Rayleigh probability density (line) compared with a typical histogram of interphase distance measurements between two DNA sequence probes (block histogram). The parameter \( \Gamma \) in the Rayleigh function was adjusted to fit the raw data. The interphase distance distribution is the result of 249 measurements between E4 and C4-46, two probes ~65 Mbp apart on chromosome 4. (B) Statistical ratios derived from distributions of interphase distances and plotted as a function of mean interphase distance. These ratios characterize the shape of a probability density. The distributions analyzed are those measured for genomic separations ranging from 0.15 to 190 Mbp on chromosomes 4, 5, and 19 using hypotonically swollen, methanol/acid fixed nuclei. The ratios are third-quartile/mean (white circles), median/mean (gray circles), and first-quartile/mean (triangles). The predicted values for a Rayleigh distribution are shown as dotted lines: third-quartile/mean = 1.33, median/mean = 0.94; and first quartile/mean = 0.61.

Statistical Distributions of Interphase Distance Follow Rayleigh Probability Densities

The linear relationship between \( \langle r^2 \rangle \) and genomic separation for distances >10 Mbp suggests that the conformation of interphase chromatin on these large scales can be described by a polymer model, as is the case at smaller distances (van den Engh et al., 1992). Another test of polymer behavior can be made by evaluating the shape of the statistical distribution measured for each probe pair. Repetitive coordinate measurements between two points on the same polymer chain, with one point placed at the origin of a Cartesian coordinate system, are expected to form a bell-shaped (Gaussian) distribution centered at zero. The distributions of distances measured between the points after projection onto any plane are expected to follow what statisticians refer to as a Rayleigh distribution (Blank, 1980; Sachs et al., 1995). The Rayleigh distribution has a probability density of the form \( P(r) = \frac{r}{\Gamma^2} \exp \left( -\frac{r^2}{2\Gamma^2} \right) \), where \( \Gamma \) is independent of \( r \). Fig. 5A shows the similarity between a Rayleigh distribution and a typical histogram of interphase distance measurements. The Rayleigh probability density has a specifically defined asymmetrical distribution that leads to characteristic ratios between means, mean-squares, medians, etc. (Sachs et al., 1995). For example, the Rayleigh distribution has a long right tail, which causes the median to be smaller than the mean by a factor of 0.94. To test whether our interphase distance measurements conform to a Rayleigh distribution, we calculated four characteristic ratios, standard deviation/mean, first quartile/mean, median/mean, and third quartile/mean, for all measured distributions. Fig. 5B plots three of these shape parameters against mean interphase distance for the data generated on methanol/acetic acid-fixed nuclei (Figs. 2 and 4). The experimental data cluster around the expected values for a Rayleigh distribution, irrespective of mean interphase distance. Slight deviation from the Rayleigh distribution is observed at distances <1.5 \( \mu \)m, which corresponds to genomic separations <4 Mbp. Table I lists the shape parameters averaged over the distributions made for each of the three chromosomes for distances...

Four shape parameters were derived from the distributions of repeated measurements of the distance between two points. Listed are the averages and standard deviations of the ratios derived from n distributions measured on the indicated chromosomes and indicated nuclear preparation. hypo-MAA 1 and 2, hypotonically swollen, methanol/acetic acid fixed (preparations 384 and 383); no hypo/MAA, methanol/acetic acid fixed, but not hypotonically swollen; no hypo/PFA, paraformaldehyde fixed, no hypotonic swelling or exposure to acids or alcohols. The column "Rayleigh" gives the statistical ratios predicted by a Rayleigh probability density, consistent with a model in which the two points are on a flexible, polymer structure (for more detail on the mathematical derivation of this prediction, see Sachs et al., 1995). The ratios in the column "Rigid, random orientation," given for comparison purposes, are predicted if the two points are at a fixed distance from each other on a rigid backbone; random orientation of the backbone in three dimensions results in a distribution of measurements in the two-dimensional plane of observation.

Data sets for genomic separations > 10 Mbp

The spread of data points around the regression lines in Figs. 2 and 4 is narrow and constant across the entire range of genomic separations. Although statistical error must account for some of this scatter pattern, we wished to determine if systematic positioning of the data points is responsible for some of the observed variation. Reproducibility in the position of data points above or below the average trend would be expected if probe sites are consistently positioned within a higher-order organizational structure. 36 probe pairs representing genomic distances ranging from 10 to 190 Mbp were analyzed on two, separately prepared batches of nuclei. For each genomic separation, we determined the deviations of individual <r^2> from the linear regression line. Fig. 6 shows that the deviations observed in the two nuclear preparations are positively correlated. The slope is 0.776, the y-intercept is 0.001, and the correlation coefficient r = 0.581. With 36 observations, the correlation probability is >0.999.

Interphase Distances Can Decrease Locally with Increasing Genomic Separation

Although the overall correlation between <r^2> and genomic separation in Figs. 2, 3, and 4 is positive, one would expect to observe local inversions in slope within this data cloud if chromatin is constrained periodically and particular DNA sequences occupy fixed positions in the resulting structure. We observed such an event using probes within a 4-Mbp region of Xq28 (Fig. 7). This region contains a 1-Mbp cluster of genes, including color vision and G6PD and two clones (p625 and p624) from the factor VIII gene, in that order (Kenrick and Gitschier, 1989). Within the 1-Mbp cluster, <r^2> increases in proportion to genomic separation (Fig. 7 B, solid symbols), with a slope very similar to that observed for chromosome 4 in this range. A negative correlation between interphase distance and genomic separation was found when we measured the dis-
Figure 7. Evidence for local inversion in slope of the mean-square interphase distance vs. genomic separation graph. (A) The map of Xq28 shows the most recent estimates of probe spacing based on cosmid walking, sequence-tagged site-content mapping and fingerprinting of yeast artificial chromosomes, pulsed field gel electrophoresis and genetic linkage data (Kenwrick and Gitschier, 1989; Poustka et al., 1991; Schlessinger et al., 1991; Palmieri et al., 1994). Cosmids (~45 kbp) were used as probes to mark the sites of c1A1, 33A31, L1CAM, the color vision genes (CV), G6PD, and two portions of the factor VIII gene, p625 and p624. The cosmid representing CV hybridizes to a tandem array of CV genes spanning >120 kbp. (B and C) The relationship between mean-square interphase distance and genomic distance in Xq28 for a subset of probe pairs. Interphase distance measurements were made on the same preparation of nuclei used for Figs. 2 and 4 (preparation 384). The data points in B are shown as white circles or black circles to correspond to the most proximal probe used in each pairwise measurement. Black circles indicate interphase distances measured among probes within the 1-Mbp cluster of genes from the color vision locus to p624 in the factor VIII gene. Measurements from the most proximal probe, c1A1, are shown as white circles. The linear distance and data point for the pair c1A1 and 33A31 are marked with the letter w. Measurements made from p624 to probes located progressively more proximal on the chromosome are shown as gray circles in C. Each data point represents an average of 179 measurements (range: 90–254). Eight probe pairs were measured independently by two

tance from points within this 1-Mbp cluster to a point known to lie significantly closer to the centromere, c1A1 (DXS374). The interphase distance measurements from c1A1 to the other Xq28 markers (nuclear preparation 384) and the generally accepted genomic separation estimates are plotted in Fig. 7 B (open symbols). With increasing genomic separation from c1A1, interphase distance first increases, and then decreases. In contrast, interphase distances from the most distal marker in the Xq28 map, p624, to points progressively closer to the centromere first increase and then, at separations >1 Mbp, appear to plateau (Fig. 7 C). In addition, c1A1 and 33A31 are very close to each other in interphase (mean = 0.55 μm), despite their separation on the linear DNA molecule of ≥1.45 Mbp.

These results confirm our earlier analyses of the folding of the Xq28 region in two other nuclear preparations (Trask et al., 1991). We reported previously that the factor VIII gene was consistently closer to the proximal markers, c1A1 and 33A31 (DXS134), than were the color vision genes (Trask et al., 1991). Since our original report, several lines of molecular and genetic evidence have been reported that convincingly support the reverse orientation (Poustka et al., 1991; Schlessinger et al., 1991; Palmieri et al., 1994) (Fig. 7 A). Thus, the Xq28 results demonstrate a situation in which interphase distance decreases as function of genomic separation.

Discussion

In the interphase nucleus, chromatin fibers follow a coiled path that cannot be followed directly. The folding of the fibers can be inferred by analyzing the two-dimensional, projected distances between DNA sequences whose positions on the linear DNA molecule are known. Our observations support a random walk/giant loop model for interphase chromatin and exclude some other models.

Random Walk/Giant Loop Model

The random walk/giant loop model is schematically illustrated in Fig. 8. Rigorous mathematical treatment of this model, with only three adjustable parameters, is provided by Sachs et al. (1995). Chromatin is organized in flexible, loose giant loops. Within each loop, the chromatin follows a random path. The loops are formed by intranuclear protein connections linking sites that are several Mbp apart (Fig. 8, points a and a'). The connections form at or near the same DNA sequences in different cells. The “loop attachment points” themselves lie along a random

---

2. The giant loops are to be distinguished from the smaller loops, on a scale of ≤100 kbp, which are supported by molecular and structural studies (Benyajati and Worcel, 1976; Mirkovitch et al., 1984). We note that various local configurations, such as winding of DNA around histones, its packing into a 30-nm fiber, local alignment with lamina (Paddy et al., 1990), and chromatin loops ≤100 kbp, are too small in scale to be studied in interphase nuclei by FISH and light microscopy.

---

individuals; their mean-square values were averaged before plotting. SEMs are not shown, but are ~4% of the mean. In both B and C, the dashed line is the best-fit linear regression through the data points ≤1.5 Mbp for chromosome 4 and is the same as the dashed line in Fig. 2.
Position b. Due to the loop structure, however, the mean-
domain walk between the loop attachment points.
of DNA sequences within a periodic, higher order organi-
ization with a giant loop/flexible backbone model. We dem-
defined by intraloop distances goes through the origin with a
like behavior of chromatin within the loops. The line de-
loops. This relationship is linear, reflecting the polymer-
ment with a slope of 0.08 μm²/Mbp extending to separations of
than that between b and e.
Measurements between randomly chosen points on the
interphase chromosome are expected to yield a cloud of observations around a biphasic relationship. This cloud has three well-described boundaries. The lower extreme is determined by distances between points close to the backbone. This boundary has a slope determined by the random walk characteristic of the backbone and a y-intercept of approximately zero. The upper boundary is determined by pairs of points both midway in their respective loops; it runs parallel to the lower boundary, but is offset by a value characteristic for the loop size. If loops form consistently near specific DNA sequences, data points will be positioned reproducibly within the cloud. The cloud’s leading edge is determined by point pairs on the same or adjacent loops. This relationship is linear, reflecting the polymer-like behavior of chromatin within the loops. The line defined by intraloop distances goes through the origin with a steeper slope than that defined by point pairs on the backbone. The boundaries for a random walk/giant loop structure with loops of ~3 Mbp have been calculated by Sachs et al. (1995) based on the data for chromosome 4. These theoretical envelopes are shown in Fig. 2.

Predictions of the Random Walk/Giant Loop Model
A chromatin model that involves two levels of random walk behavior leads to several predictions. The distance between points within a loop (Fig. 8, among points c-f) is expected to increase with a characteristic determined mainly by the properties of the loop chromatin. If chromatin folding within the loop is random, then mean-square interphase distance and genomic separation are linearly related over distances less than several Mbp. The distance between points close to the backbone (points a and i) is determined mainly by the characteristics of the backbone. If the backbone is a flexible, randomly folding structure, a linear relationship between mean-square interphase distance and genomic separation is again expected. The distance between points separated by several loops (points a and j) depends on their respective distances to the nearest loop attachment point and on the distance along the random walk between the loop attachment points.

Note that, over intermediate scales, interphase distance may inversely relate to separation along the looping DNA strand. The correct order is c, d, e, f, and g viewing from position b. Due to the loop structure, however, the mean-

Measurements between randomly chosen points on the
interphase chromosome are expected to yield a cloud of observations around a biphasic relationship. This cloud has three well-described boundaries. The lower extreme is determined by distances between points close to the backbone. This boundary has a slope determined by the random walk characteristic of the backbone and a y-intercept of approximately zero. The upper boundary is determined by pairs of points both midway in their respective loops; it runs parallel to the lower boundary, but is offset by a value characteristic for the loop size. If loops form consistently near specific DNA sequences, data points will be positioned reproducibly within the cloud. The cloud’s leading edge is determined by point pairs on the same or adjacent loops. This relationship is linear, reflecting the polymer-like behavior of chromatin within the loops. The line defined by intraloop distances goes through the origin with a steeper slope than that defined by point pairs on the backbone. The boundaries for a random walk/giant loop structure with loops of ~3 Mbp have been calculated by Sachs et al. (1995) based on the data for chromosome 4. These theoretical envelopes are shown in Fig. 2.

Experimental Observations
Our data on human interphase chromosomes are in agree-
maintain with a giant loop/flexible backbone model. We dem-
strate: (a) distance distributions that conform to the Rayleigh distribution, indicating overall random folding; (b) a striking biphasic relationship between mean-square interphase distance and genomic separation, indicating two levels of random walk polymer behavior; (c) a narrow and reproducible spread of data points around the biphasic relationship, consistent with the systematic positioning of DNA sequences within a periodic, higher order organi-

Figure 8. A random walk/giant loop model for interphase chromosomes. See Discussion for a detailed explanation, and Sachs et al. (1995) for a mathematical description. The chromatin follows a much longer, more tortuous path than the path schematically shown here. In the model, chromatin is organized in giant loops, i.e., loops containing several Mbp of DNA. Loop attachment points, such as a and a', are connected by as yet unidentified proteins. Chromatin follows a loose, random walk within each loop. Loop attachment points also lie on a random walk, termed here the backbone. The relative length of the chromatin and protein portions of the backbone is unknown. Note that local configurations involving <100 kbp or <0.25 μm are too small in scale to appear in the figure or to be analyzed in interphase nuclei by FISH and light microscopy.

Statistics of Pair-wise Distance Measurements.
The shape parameters of the distance distributions are one indication that the chromatin folds with a large degree of randomness. The experimental values on three different chromosomes closely match the shape parameters of the Rayleigh probability density, which is characteristic for random walks (Table I). Significantly, the shape parameters do not depend on genomic separation >10 Mbp (Fig. 5) or fixation method (Table I). Other distributions, such as ones obtained by measuring between two points held a fixed distance apart in three dimensions, but projected randomly onto the measurement plane, yield very different values (Table I, last column).

Biphasic Relationship. The relationship of mean-square interphase distance (<r²>) and genomic separation is biphasic (Figs. 2 and 3). For human chromosome 4, <r²> rises initially with a rate of 1.9 μm²/Mbp. This relation changes abruptly around 2 Mbp to a second linear phase with a slope of 0.08 μm²/Mbp extending to separations of ~200 Mbp. Data on chromosomes 5 and 19 are in general agreement with this picture (Fig. 4). The sharp transition indicates that chromatin follows a loose random walk path.
for some number of steps, but is regularly constrained by connections between points several Mbp apart. Given the positive slope of the second phase, these connection points must also lie along a random walk path.

Reproducible Spread of the Data Points. The data points in Figs. 2 and 4 fall within a band of constant width around the regression lines, providing an important indication of a systematic, looped structure. Without systematic constraints, the spread of data points is expected to increase with increasing genomic separation. The excellent fit of the data within the theoretical boundaries (Fig. 2) supports the existence of sequence-specific, rather than random, loop attachment points. Moreover, measurements made on two, independent nuclear preparations are correlated (Fig. 6), indicating that some DNA sequences are systematically closer together or farther apart than the average for their genomic separation. This reproducible deviation is consistent with a model in which loops form relatively consistently near particular DNA sequences.

Local Inversion in Slope. Further support for giant loops comes from observations in Xq28 (Fig. 7). One interpretation for the close physical proximity, but large genomic separation, of clA1 and 33A31 is that they both lie close to the backbone (Fig. 8, points h and i). A local inversion in slope is also observed in Xq28, as predicted by a model in which chromatin takes a path away from and then returns to a backbonelike structure. With increasing genomic separation from clA1, interphase distance increases and then decreases (Fig. 7 B). This negative correlation suggests that clA1 is near the backbone on one loop (Fig. 8, point i), and the other markers are on a neighboring loop (points g, c, with the color vision genes furthest from the backbone). Measurements made in the other direction from p624 increase and then briefly plateau as expected (i.e., c to d–i). This simple geometric configuration is consistent with the model based on our interpretation of Figs. 2–6. A “bend” in the interphase configuration of a 2.4-Mbp YAC observed by den Dunnen et al. (1992) is also consistent with this model.

Our results have implications for the use of interphase FISH for physical mapping (Trask and co-workers, 1991b, 1993b). Interphase distance will be most useful for estimating relative genomic separations <1 Mbp, where the relationship is steep. However, care should be exercised even when a clear probe order emerges in interphase; a looped configuration may invert the order relative to the sequence on the DNA molecule.

Nature of the Flexible Backbone

In the schematic representation of the model, the backbone is drawn as alternating protein links connecting points averaging ~3 Mbp apart and short chromatins links between neighboring loops. The chromatins links are analogous to, but on a much larger scale than, linker DNA between nucleosomes. We have no information regarding the relative lengths of the protein and DNA components of the proposed backbone. The protein links could be very short, in which case the backbone would be composed almost entirely of chromatins links as long as ~0.2 Mbp. Alternatively, the chromatins links could be very short, and the random walk properties of the backbone could depend primarily on the connective proteins. It may be possible to identify additional candidate loop attachments, sequences with interphase behavior analogous to clA1’s, and examine them for common sequence or protein affinity properties. It is tempting to speculate that the recently described coiled coil proteins, which have similarity to motor molecules (Strunnikov et al., 1993; Chuang et al., 1994; Hirano and Mitchison, 1994), might sit along the backbone and reel in the giant loops to form condensed mitotic chromosomes. It may not be coincidental that high resolution metaphase bands also contain ~3 Mbp of DNA.

Chromosome Domains in the Nucleus

Our measurements support the concept that the nucleus is partitioned into irregularly shaped chromosomal domains. Use of whole-chromosome paints has led to a similar conclusion, but concerns have lingered that these paint labels reveal the bulk of a chromosome and overlook its far-reaching, diffuse regions. By repeatedly measuring between specific points on a chromosome, we can determine the average size of its domain. Maximal intrachromosomal distances are short (4.5 μm) compared to nuclear dimensions (27 by 13 μm). Thus, a single chromosome does not expand to occupy the whole nuclear volume. The long distance scale factor of chromatin is ~0.065 μm2/Mbp (average of chromosomes 4 and 5). For the whole genome, the corresponding area is 390 μm2 (6 × 103 Mbp × 0.065 μm2/Mbp), which, after accounting for 2-axial overlap and interdigitation of domains, agrees well with an average nuclear area of 280 μm2.

Intrachromosomal distances did not reach a plateau, as expected if chromosomal volume was restricted by external boundaries (Hahnfeldt et al., 1993). We find no evidence for a rigid, Rabl-like configuration of mammalian interphase chromosomes, as might have been anticipated from observations of prometaphase chromosomes in Drosophila (Hiracka et al., 1990a). Given the random geometry of the chromosome as a whole, systematic compartmentalization within the chromosomal domain, for example in gene-rich and gene-poor subregions, as suggested by Cremer et al. (1993), also appears unlikely. Our findings do not preclude attachment of specific sequences to the nuclear matrix, envelope, or other nuclear components, but they indicate that these attachments do not constrain the chromosome into a nonrandom conformation.

Relevance of our Findings to the Organization of Chromosomes In Vivo

To obtain these data, FISH is used to label specific single-copy DNA sequences in fixed nuclei. The effects of fixation and FISH on nuclear structure are not completely understood. However, there are several indications why our observations may be a valid representation of the native organization. (a) Sequence-specific, systematic organization and reproducibility are observed characteristics likely to be inherent to the nuclei and unlikely to result from the fixation and FISH processes alone. (b) Hallmarks of random walk/giant loop organization (biphasic relationship and Rayleigh distributions) were found in three, alternatively fixed nuclear preparations. (c) It is unlikely that significant distortions in chromosomal geometry on scales..
relevant to the giant loop and flexible backbone aspects of the model (>1 μm) could result from the fixation and FISH processes. Indeed, the DAPI staining pattern, a crude measure of gross nuclear morphology, was unchanged by denaturation and FISH. (d) The relative positions of homologous chromosomes, another measure of large-scale organization, are independent of fixation conditions (Hirakura et al., 1993; Yokota, H., R. Sachs, G. van den Engh, and B. Trask, manuscript in preparation). It is formally possible that additional hierarchical levels exist in vivo on scales >100 kbp, with FISH selectively eliminating these organizational levels, but leaving evidence for giant loops. The difficult issues that arise in relating prepared samples to in vivo configurations will undoubtedly take time to resolve, as has been the case in studies of smaller-scale chromatin structure (van Holde, 1989) or mitotic chromosome structure (e.g., Rattner and Lin, 1985).

Conclusions

We have shown that measurements between the sites of specific DNA sequences give quantitative information about the large-scale geometry of chromatin during the G0/G1 phase of the cell cycle. For the three chromosomes studied, the data indicate two, and apparently only two, levels of higher-order chromatin structure at scales >0.15 Mbp. The simplest model that fully describes the spatial relationships we observe is that of flexible chromatin loops of several Mbp arranged along a tighter chromosomal backbone. Folding within each loop and of the backbone is dominated by random influences. Other models discussed by Sachs et al. (1995) are also consistent with the data, but are more complicated and require additional parameters for their description.

Our description of chromatin folding is the first step in understanding how large-scale structure affects or is affected by cellular processes. Further elucidation of interphase organization will require detailed maps and associated DNA clones. For example, measurements among probes placed every ~200 kbp for spans of ~10 Mbp are needed to support further discussions about the sequence specificity of loop formation, or to determine if regional differences exist in loop size or compaction. A future challenge will be to determine the composition and relative contribution of the protein and chromatin links between loops to the total length of the backbone random walk. Further intrachromosomal measurements may also help us to understand how chromosomes decondense and recondense during the cell cycle or how interphase geometry is affected by transcriptional activity.

We thank the colleagues named in Materials and Methods for generously providing probes for our study, Anne-Marie Poustka (Deutsches Krebsforschungszentrum, Heidelberg, FRG) and David Schlessinger (Washington University, St. Louis, MO) for communicating unpublished Xq28 map information, Michael Botchan (University of California, Berkeley, CA) for critically reading an earlier version of the manuscript, and, at the University of Washington, Myron Peto, Hillary Massa, and Cynthia Friedman for technical assistance, and Richard Esposito and Brian Pinkerton for developing software for interfacing a computer to the digitizing board and data analysis. We also thank Tom Donnelly at Applied Precision, Inc., for advice and access to the DeltaVision instrument.
