The \textit{Chlamydomonas} Kinesin-like Protein FLA10 Is Involved in Motility Associated with the Flagellar Membrane

Keith G. Kozminski, Peter L. Beech, and Joel L. Rosenbaum
Department of Biology, Yale University, New Haven, Connecticut 06511

\textbf{Abstract.} The \textit{Chlamydomonas} FLA10 gene was shown to encode a flagellar kinesin-like protein (Walther, Z., M. Vashishtha, and J. L. Hall. 1994. \textit{J. Cell Biol.} 126:175–188). By using a temperature-sensitive allele of FLA10, we have determined that the FLA10 protein is necessary for both the bidirectional movement of polystyrene beads on the flagellar membrane and intraflagellar transport (IFT), the bidirectional movement of granule-like particles beneath the flagellar membrane (Kozminski, K. G., K. A. Johnson, P. Forscher, and J. L. Rosenbaum. 1993. \textit{Proc. Natl. Acad. Sci. (USA)}. 90:5519–5523). In addition, we have correlated the presence and position of the IFT particles visualized by light microscopy with that of the electron dense complexes (rafts) observed beneath the flagellar membrane by electron microscopy. A role for FLA10 in submembranous or flagellar surface motility is also strongly supported by the immunolocalization of FLA10 to the region between the axonemal outer doublet microtubules and the flagellar membrane.

Initial studies aimed at identifying the motors driving gliding, bead movement, and IFT revealed multiple kinesin-like proteins (kips) within the flagella of \textit{Chlamydomonas} (Fox et al., 1992; Kozminski et al., 1992; Kozminski, 1995a). Individual kips were subsequently localized by immunohistochemical methods to specific subsets of flagellar microtubules (reviewed in Bernstein and Rosenbaum, 1994). Among the nine outer doublet and two central pair microtubules of the flagellar axoneme, two kips were localized by immunoelectron microscopy to the central pair microtubules, though it was not clear if both kips were on the same microtubule (Bernstein et al., 1994; Johnson et al., 1994). The presence of a third central pair-associated klp was detected in an immunoblot analysis of wild-type flagella and mutant flagella lacking the central pair apparatus (Fox et al., 1994; Johnson et al., 1994). This analysis further suggested that an additional flagellar klp was associated with the outer doublet microtubules. The putative outer doublet-associated klp, initially identified immunoelectronically, also had the biochemical properties of kinesin, such as an ATP-dependent release from axonemal and brain microtubules (Fox et al., 1994). In comparison to the central pair-associated kips, the proximity of this klp to the flagellar membrane made it the best candidate among the flagellar kips for a motor involved in bead movement and IFT (Fox et al., 1994).

Concurrent with the studies just described, Walther et al. (1994) cloned the \textit{Chlamydomonas} FLA10 gene and showed that it encoded a flagellar klp. The FLA10 locus was first identified in screens for mutants that failed to regenerate or maintain stable flagella at 32°C (Huang et al., 1977; Adams et al., 1982). More than a dozen tempera-
Materials and Methods

Cultures

Chlamydomonas moewusii strain M475 (CC957) and C. reinhardtii strains 21gr (CC1690), pfl (CC1024), and fla10-1 (CC1919) were obtained from the Chlamydomonas Genetics Center (Duke University, Durham, NC). The strain fla10-1 was originally designated dc-a-224 and is temperature-sensitive due to a single genetic lesion (Huang et al., 1977). Log-phase, synchronously dividing cultures were grown in minimal medium (M) (Sager and Granick, 1953) at 22-23°C on a 14:10 h light/dark cycle with continuous aeration.

Crosses

To facilitate the observation of flagella by light microscopy, fla10-1 was crossed into a pfl background. pfl cells, which are deficient in radial spoke protein 4 and thus the radial spoke head, have flaccid, paralyzed flagella (Lewald et al., 1977; Piperno et al., 1977; Huang, 1986; Orty et al., 1992) that are amenable to video analysis (Kozminski, 1995b). Gametes were made from synchronized, vegetative M1 cultures and mated as previously described (James, 1989). Phase-contrast microscopy was used to screen the progeny of dissected tetrads for immotile (paralyzed-flagella) cells in synchronous M1 cultures. To identify progeny bearing the temperature-sensitive fla10-1 allele, aliquots of synchronously-growing cells were placed in test tubes and incubated for 4 h at 20°C and 32°C; the cells were then examined by phase microscopy for the presence of flagella. pfl fla10-1 double mutants retained their flagella at 20°C, but like the parental fla10-1 strain, not at 32°C.

Flagellar Resorption

To induce flagellar resorption at the permissive temperature, cells were pelleted, washed with low calcium/high sodium M medium (no CaCl₂, 25 mM sodium citrate), repelleted, and then resuspended once again in low calcium/high sodium M medium (Lefebvre et al., 1978). In an alternative method, cells were pelleted, washed with M medium, repelleted, and then resuspended in M medium containing 0.5 mM 3-isobutyl-1-methyl-xan-thine (IBMX; Sigma, St. Louis, MO) (Lefebvre et al., 1980). With fla mutants, flagellar resorption was also induced by shifting the cultures from the permissive (20°C) to restrictive temperature (32°C) (Huang et al., 1977; Adams et al., 1982; Lux and Dutcher, 1991).

Flagellar Length Measurements

To measure flagellar length in time course experiments that did not involve flagellar isolation, cells were pelleted and then resuspended to a final concentration of 1-2 × 10⁶ cells/ml in M1 medium or treated as described above to induce flagellar resorption. The cells were transferred to glass test tubes and gently agitated at 50 rpm under continuous light at either 20°C or 32°C in an AquaTherm water bath shaker (New Brunswick Scientific, New Brunswick, NJ). Aliquots were removed and fixed with Lugol’s solution (6% KI, 4% sodine in water). 30-50 flagella per sample were measured on a Zeiss phase-contrast microscope calibrated with a stage micrometer.

Quantitation of Flagellar Surface Motility

To quantify flagellar surface motility, log-phase cultures, grown synchronously in M1 medium, were centrifuged for 5-10 min at 1,500 rpm in an IEC centrifuge. The cell pellets were resuspended to a final concentration of 3.5 × 10⁶ cells/ml in fresh M1 media or treated as described above to induce flagellar resorption. 40 µl of cells were mixed with either 120 µl M1 medium, M2 medium with 0.5 mM IBMX, or low calcium/high sodium M1 medium, and 40 µl of a 1:10 dilution of polystyrene beads each prewarmed to either 20 or 32°C. The polystyrene beads (0.3-µm diam; Polysciences, Inc., Warrington, PA) were prepared by washing four times with double distilled water (Bloodgood, 1995). Bead movement on the flagellar surface was immediately scored using a phase-contrast microscope. The number of flagella examined, number of beads bound, and number of beads moving were recorded over a period of 3 min.

Video Microscopy

In preparation for video microscopy, cells were resuspended in fresh M1 medium and placed between two No. 1 coverslips (Corning Inc., Corning, NY) supported with 0.5-mm plastic shims. Vaseline was used to seal the chamber. A Zeiss Axiosvert microscope fitted with DIC optics was used for all experiments. The preparation of coverslip chambers, optics, and method of digital data acquisition have been detailed previously (Kozminski et al., 1993b; Kozminski, 1995b). For temperature-shift experiments, the cells were heated to the permissive temperature (20°C) or restrictive temperature (32°C) within the coverslip chamber. Heat was transferred to the chamber by warming both the condenser and objective with Kaption heaters, 0.5 × 4 in. 5W, 25V and 1 × 3 in, 7.5W, 28V, respectively (Electroflex Heat Inc., Bloomfield, CT); the chamber temperature was controlled by manually adjusting the current through the heaters. To measure the internal temperature of the chamber to ± 0.1°C, a 0.009-in Type T Tissue Implant Probe (Cole-Parmer, Niles, IL) connected to a Digi-Sense thermometer (Cole-Parmer, Niles, IL) was inserted into the chamber.

Electron Microscopy

For the analysis of rafts between the flagellar membrane and axoneme, vegetative cells were pelleted and resuspended to a concentration of 3.5 × 10⁶ cells/ml in 10 mM Hepes-KOH, pH 7.4. The cells were either left untreated or induced to resorb their flagella as described above. Cells were fixed, processed, and embedded as previously described (Kozminski et al., 1993b), but were not included in a block of low melting temperature agarose after fixation. Addition of 0.8% K₂Fe(CN)₆ to the postfixation step greatly enhanced the ability to visualize rafts. Silvergold thin sections were cut with a diamond knife, stained with 2% (wt/vol) uranyl acetate for 30 min, washed 4 times with double distilled water, stained with Reynolds' lead citrate (Reynolds. 1963) for 4 min, and washed 4 times with double distilled water. Thin sections were examined on a Zeiss EM10 transmission electron microscope. For determining the number of rafts between the flagellar membrane and axoneme, control and experimental grids were scored blind. Rafts were scored only in transverse sections of flagella.

Single Cell Light and Electron Microscopy

Cells were fixed and embedded as described above; however, before poly-

---

2. The FLA10 gene product was originally named KHP1 for kinesin-homologous protein 1 (Walther et al., 1994). For consistency with the newly adopted standard of genetic nomenclature for Chlamydomonas (Dutcher, 1995), we suggest that FLA10 be used to represent the FLA10 gene product.
merization of the resin, cells were sandwiched between two teflon-coated glass microscope slides (Fluorogride CP, Electron Microscopy Sciences, Ft. Washington, PA). After polymerization, the slides were separated with a razor blade. A thin wafer of resin (~0.5 mm thick) was peeled from the slides and affixed at its corners to an acid-washed No. 1 coverslip with Duro SuperGlue (Loctite Corporation, Cleveland, OH); the flat-embedded cells were observed by video-enhanced DIC microscopy. The optics and methods of digital data acquisition and image enhancement have been detailed previously (Kozminski et al., 1993b; Kozminski, 1995b). The relative position of the cell of interest was diagrammed, and a resin chip containing the cell was excised and mounted on a block for thin-sectioning. Serial sections through the flagellar region were collected, stained, and observed as described above. To spatially correlate IFT particles and rafts, electron and light micrographs were enlarged to equivalent sizes using the flagellar tip and the apical papillum of the cell as reference points. Rafts were marked on acetate overlay tracings that were compiled from electron micrographs of the complete series of flagellar sections. Some error would be expected in this process, primarily from differential section shrinkage. The fact that the IFT particles visible in the light microscope align with rafts to within less than 0.25 μm makes us confident that the observed correlation is accurate.

Flagellar Isolation and Fractionation

Two standard methods of flagellar isolation and fractionation were employed with modification. For the STEEP + Ca2+ method (Witman et al., 1972), 8 l of cells were concentrated by centrifugation. After deflagellation, deflagellated cells and flagella were added to 250-ml conical bottles and underlaid with 50–75 ml of 25% sucrose (wt/vol) in STEEP (0.15 M sucrose, 15 mM Tris-C1, pH 7.8, 2.5 mM EDTA, pH 7.8, 11% (vol/vol) ethanol, and 30 mM KCl) and 15 mM CaCl2. Cells bodies were removed by centrifuging for 10 min at 1,600 rpm at 0°C in an IEC 259 rotor (no brake). The suspension of flagella above the cushion was collected and the flagella were pelleted for 20 min at 10,000 rpm at 4°C in a Sorvall SS-34 rotor. Flagellar pellets were resuspended in 5–6 ml HMDEK (10 mM Hepes-KOH, pH 7.2, 5 mM MgSO4, 1 mM DTT, 0.5 mM EDTA, pH 7.2, 25 mM KCl), transferred to 12-ml conical Pyrex tubes, and underlaid with an equal volume of 25% sucrose (wt/vol) in HMDEK. Any cell bodies remaining in the preparation were removed by centrifuging for 10 min at 4°C at 1,500 rpm in an IEC centrifuge. The suspension of flagella above the cushion was collected and the flagella pelleted for 10 min at 4°C at 8,000 rpm in a Sorvall HB-4 rotor. Flagellar pellets were resuspended in HMDEK containing 1 mM PMSF, 5 μg/ml pepstatin A, 2 μM taxol to stabilize the central pair microtubules, and 1% NP-40 to solubilize the flagellar membrane. Axonemes were pelleted for 10 min at 4°C at 8,000 rpm in a microfuge. The supernatant containing the detergent soluble membrane + matrix fraction was collected and the axonemes were resuspended in HMDEK with PMSF, pepstatin A, and 10 μg/ml taxol. Axonemes were pelleted as before and washed in HMDEK with PMSF and pepstatin A.

A modified version of the pH-shock method (Witman et al., 1972) was used to isolate flagella during time course experiments at 32°C. Cells from 16 l of synchronous M1 culture were concentrated with a Pellicon filtration system (Millipore, St. Louis, MO) and dNTPs (1 mM final) to a total volume of 20 μl; reverse transcription was performed at 42°C for 45 min and the resultant cDNA was used for PCR amplification as described (Bernstein et al., 1994). First round PCR was primed with CGATGTCGGGTAGTCCTGCC (FLA10 anti-sense nucleotides 2236–2215) and GATGGCTCCGTTCCAGG (FLA10 sense nucleotides 1098–1119). A product of the predicted size was synthesized, gel purified, and primed with GCA-ATTCTGAAGCCCTGTCG (FLA10 anti-sense nucleotides 2064–2046) and GACATGAGGCTCAAGG (FLA10 sense nucleotides 1246–1264). The second round of PCR (an 819-bp fragment 1246–2046) was gel purified, treated with T4 DNA polymerase and T4 polynucleotide kinase (New England Biolabs, Beverly, MA), and subcloned into the EcoRV site of pBluescript II KS+ (Stratagene, San Diego, CA). Individual clones were isolated and sequenced; the clone chosen for further work differed from FLA10 (Witman et al., 1994) by a single silent mutation (an A to G transition) at position 1518. The cloned fragment was then excised using the BamHI and HindIII sites of pBluescript and inserted into the corresponding sites of the His fusion vector pQE30 (QIAGEN Inc., Chatsworth, CA).

Antibodies

FLA10 antibody was raised against amino acids 416–688 of the unique COOH-terminal tail region of FLA10, which was expressed in E. coli as a His6-FLA10 fusion protein (above). Recombinant protein was purified from E. coli strain XL1 Blue as described (Bernstein et al., 1994). Polyclonal antibody A5 against an NH2-terminal decapeptide of Volvox actin A was the gift of D. Kirk (Washington University, St. Louis, CA). Polyclonal antibody A5 against an NH2-terminal decapeptide of Volvox actin A was the gift of D. Kirk (Washington University, St. Louis, MO) and Rüdiger Schmitt (University of Regensburg). Affinity-purified polyclonal Chlamydomonas KLPI tail antibody was described previously (Bernstein et al., 1994).

Immunoelectron Microscopy

For postembedding immunolocalization, wild-type 2gr cells were fixed in 0.75% glutaraldehyde in 20 mM Pipes (pH 7.1) on ice for 30–40 min. A loose pellet of fixed cells was washed in buffer, dehydrated to 80% ethanol, and embedded in LR Gold (London Resin Company, Hampshire, UK) at −20°C for 36 h. The LR Gold was polymerized at −20°C under white fluorescent light with 0.2% (wt/vol) benzil as the catalyst. Silver-gold thin-sections were collected on collodion or formvar-coated nickel grids, blocked and immunolabeled as previously described (Bernstein et al., 1994). Affinity-purified LAGSE antibody was used at a 1:1,000 dilution and affinity-purified FLA10 antibody was used at a 1:100 dilution; the primary antibodies were detected with 12-nm colloidal gold conjugated to goat anti-rabbit IgG (Jackson Immunoresearch, West Grove, PA). Labelled sections were stained with 2% aqueous uranyl acetate for 5 min, rinsed for 10 s with distilled water, and wipped dry.

Cessation of Beat-independent Flagellar Motilities in fla10 Cells at 32°C

To determine whether the flagellar kinesin-like protein

Kozminski et al. FLA10 Function and Localization

1519
motility, we examined the temperature-sensitive *Chlamydomonas fla10-1* (hereafter called *fla10*) mutant by video-enhanced DIC microscopy. The motility of particular interest was IFT, a beat-independent flagellar motility that we recently described in *Chlamydomonas* as the bidirectional movement of particle-like material beneath the flagellar membrane (Kozminski et al., 1993b). It was suggested (Kozminski et al., 1993b; Fox et al., 1994; Walther et al., 1994) that IFT (Fig. 1 a) is driven by a flagellar klp, in at least one direction, along the length of the flagellum. To facilitate the observation of flagella in motile *pf flalO* cells, the motile *fla10* mutant was crossed with the paralyzed-flagella mutant *pf1*.

At the permissive temperature (20°C), both *pf1* cells and the *pf1 fla10* double mutant exhibited IFT and polystyrene bead movement on the flagellar surface (Table I). The submembranous particles characteristic of IFT moved bidirectionally along the flagella of both *pf1* and *pf1 fla10* cells at similar rates (data not shown). IFT was more difficult to visualize, however, in the double mutant because fewer particles were observed moving in the flagella of *pf1 fla10* cells as compared to *pf1* cells. The reduced number of IFT particles observed in the flagella of *pf1 fla10* cells at 20°C was consistent with the report that cells bearing *fla10* alleles can display partial nonconditional mutant phenotypes (Lux and Dutcher, 1991). Motility on the flagellar surface was also very similar between *pf1* and *pf1 fla10* cells at 20°C (Table I). 45 and 50% of the polystyrene beads that bound to the flagellar surface of *pf1* and *pf1 fla10* cells, respectively, were observed moving along the length of the flagellum. The rate of bead movement and the percentage of beads moving approximated that reported for other *Chlamydomonas* strains (Bloodgood, 1977; Bloodgood et al., 1979; Kozminski et al., 1993b).

When *pf1 fla10* cells were shifted from the permissive temperature (20°C) to the restrictive temperature (32°C), both IFT and bead movement ceased completely within 60–90 min (Table I), although bead adhesion to the flagellar membrane was not affected. The first notable loss of IFT in *pf1 fla10* cells was evident by 30 min at 32°C (data not shown), which is the same period of time when *fla10* cells lose the ability to assemble new flagella at 32°C if experimentally deflagellated (Huang et al., 1977), suggesting that IFT is required for flagellar assembly. With *pf1* control cells, IFT, bead movement, and gliding motility continued normally at the restrictive temperature (Table I). Gliding motility in the *pf1 fla10* cells could not be assessed, however, because these cells adhered poorly to coverslips at both 20 and 32°C. With the *pf1 fla10* cells at 32°C, the loss of IFT and bead movement in both directions was gradual, concomitant, and equal along the length of the flagella. The cessation of IFT was observed specifically as a decrease in the number of particles moving along the length of the flagella, rather than as a decrease in the rates of particle movement. After the complete cessation of IFT (60–90 min at 32°C), only a minimal recovery of IFT was observed when *pf1 fla10* cells were shifted down to the permissive temperature for 3–4 h.

Depending upon the allele, the flagella of *fla10* cells resorb asynchronously and completely within 5–24 h after the shift from 20 to 32°C, with the onset of flagellar resorption either being immediate upon temperature shift or delayed several hours (Huang et al., 1977; Adams et al., 1982; Dutcher, 1989; Lux and Dutcher, 1991; this study). As expected for cells bearing the *fla10-1* allele at 32°C (Huang et al., 1977; Dutcher, 1989; Walther et al., 1994), flagellar resorption began after a lag of ∼60 min (see Fig. 4 a and data not shown). In the *pf1 fla10* double mutant, however, the initiation of flagellar resorption began immediately upon shifting to 32°C (see Fig. 4 a and data not shown). This premature temperature-induced flagellar shortening in the double mutant was not unexpected because *pf1* cells in minimal medium have also been shown to immediately undergo temperature-induced flagellar resorption, albeit at a substantially slower rate than *fla10-1* cells (Jarvik and Rosenbaum, 1980). When the flagella of *pf1 fla10* cells were induced to resorb with IBMX at 20°C (Lefebvre et al., 1978), bead movement and IFT continued normally...
rafts observed by electron microscopy. The presence and absence of rafts did correlate with the presence and absence of IFT particles observed moving by DIC microscopy, suggesting that the particles observed moving by DIC microscopy are indeed the dense complexes or “rafts” beneath the flagellar membrane (Fig. 1, b–d). We previously hypothesized (Kozminski et al., 1993b) that the IFT particles observed by light microscopy were the rafts observed by electron microscopy. fla10, pfl fla10, and pfl cells were incubated at both the permissive and restrictive temperatures, fixed, and thin-sectioned for a quantitative EM analysis of the rafts.

+++, ++, and – represent the number of IFT particles observed by video-enhanced DIC microscopy for fixed, unembedded cells when viewed by video-enhanced DIC microscopy before thin-sectioning. Although the resin decreased resolution, the flagellar topology of these flat-embedded cells when viewed by video-enhanced DIC microscopy was indistinguishable from that of fixed unembedded cells. Fig. 2 a shows three prominent IFT particles (labeled 1, 2, and 3) in a flagellum of a flat-embedded cell. When serial thin sections of the same cell were examined by electron microscopy (Fig. 2, b–d) and aligned with the video-enhanced DIC image shown in Fig. 2 a, the positions of the three prominent IFT particles corresponded to the positions of rafts (labeled 1, 2, and 3, respectively) beneath the flagellar membrane. This alignment indicates that the rafts observed by electron microscopy are the IFT particles observed by video-enhanced DIC microscopy.

Immunoblots of flagellar fractions probed with anti-klp antibodies. Wild-type (21gr) axonemes (A) and the membrane + matrix fraction (M) were loaded stoichiometrically. Axonemal lanes contain 15 μg of total protein.

Figure 3. Immunoblots of flagellar fractions probed with anti-klp antibodies. Wild-type (21gr) axonemes (A) and the membrane + matrix fraction (M) were loaded stoichiometrically. Axonemal lanes contain 15 μg of total protein.

To obtain a probe that specifically recognizes FLA10, we raised a polyclonal antibody against a bacterially expressed, nonconserved region of the FLA10 tail (see Material and Methods). On immunoblots, the affinity-purified FLA10 antibody recognized a single polypeptide of ~90 kD in the axonemal fraction of detergent-extracted Chlamydomonas flagella (Fig. 3, lane 3). This 90-kD polypeptide comigrated with an axonemal polypeptide recognized by the LAGSE antibody (Fig. 3, lane 1); both polypeptides were extractable with 10 mM MgATP (data not shown) and were clearly distinguishable from KLP1 (Fig. 3, lane 5), a 97-kD central pair-associated klp (Bernstein et al., 1994) that was also extractable with 10 mM MgATP (data not shown). Like the ATP-extractable ~90-kD axonemal polypeptide recognized by 14-02, an antibody raised against a smaller portion of the nonconserved tail region of FLA10 (Walther et al., 1994), the 90-kD ATP-extractable axonemal polypeptide recognized by the FLA10 antibody is also reduced in the flagella of fla10-1 cells in comparison to control cells (see Fig. 4 b, bottom; Fig. 7 in Walther et al., 1994), strongly suggesting that the FLA10 antibody recognizes the same polypeptide as 14-02.

FLA 10 Levels In The Flagella During Temperature-Induced Flagellar Resorption

The simplest explanation for the temperature-sensitive phenotype of fla10 cells is the destabilization of FLA10 at elevated temperatures, leading to the inactivation and/or rapid degradation of FLA10. Among the Chlamydomonas strains temperature-sensitive for flagellar assembly and stability, the sensitivity of a mutant polypeptide to temperature can vary depending upon its location within the cell (Huang et al., 1977; Shiota et al., 1979). In a series of experiments that used flagellar length as an indicator of FLA10 function, FLA10 appeared to be irreversibly destabilized by elevated temperatures in both the flagella and the cell body of fla10 cells (data not shown). To test for
temperature-induced destabilization of FLA10 in flagella, we took advantage of the fact that *Chlamydomonas* cells can reuse flagellar polypeptides, which have been resorbed into the cell body, for the assembly of new flagella (Coyne and Rosenbaum, 1970; Lefebvre et al., 1978). Gametes, which have a very small precursor pool (Lefebvre et al., 1978), were induced to resorb their flagella (low calcium/high sodium medium) at 32°C in the presence of cycloheximide, an inhibitor of protein synthesis. When shifted down to 20°C, fla10 gametes, unlike wild-type gametes, could not regenerate their flagella utilizing the precursor pool of 32°C-treated polypeptides obtained from flagella resorbed at 32°C. These results indicated that FLA10 was irreversibly destabilized in the flagella of the fla10 mutant and that the removal of cycloheximide (i.e., new protein synthesis) was required for the assembly of new flagella. FLA10 was also shown to be irreversibly destabilized by elevated temperatures when it is located in the cell body. It is known that when vegetative wild-type (21gr) cells are deflagellated in the presence of cycloheximide, half-length flagella can be assembled from a pool of precursors located within the cell body (Rosenbaum et al., 1969); this is also true for fla10 cells at 20°C. However, when fla10 cells were incubated for 45 min at 32°C in 10 μg/ml cycloheximide and then deflagellated, no flagellar regeneration occurred, even after cells were shifted down to 20°C (see also, Dutcher, 1986).

The antibody specific for FLA10 enabled us to monitor, on immunoblots, the amount of FLA10 in flagella isolated from cells maintained at 20 and 32°C for varying periods of time. An actin antibody was used to reprobe the same immunoblots to demonstrate equivalent sample loads (Fig. 4b). FLA10 levels were considerably reduced, even at the permissive temperature, in the flagella of fla10 cells as compared to pfl cells (Fig. 4b, bottom, compare 0 time points). The cause of this reduction in fla10 cells could be due to a decreased level of FLA10 synthesis, the rapid degradation of FLA10, or the failure of FLA10 to enter the flagellum. Because the flagella of fla10 cells appeared structurally (i.e., length and rafts; see Fig. 4a and Table II, respectively) and functionally (i.e., beating) intact at 20°C, albeit with a greatly reduced amount of FLA10 in comparison to pfl control cells, it may be that more FLA10 per flagellum is necessary to maintain flagellar structure and function at elevated temperatures. This hypothesis is supported by the observations made when pfl and fla10 cultures were shifted from 20 to 32°C: for the period of the experiment, the flagella of pfl cells maintained a constant length (Fig. 4a) and exhibited an increased amount of FLA10 (Fig. 4b); whereas, the flagella of fla10 cells lost flagellar length (Fig. 4a) and maintained a very low level of FLA10 (Fig. 4b, bottom). The flagella of pfl fla10 cells, however, produced different results. At time 0, FLA10 levels in the flagella of pfl fla10 cells approximated control levels (compare 0 time points of pfl and pfl fla10) and then declined 40-80 min post-temperature shift (Fig. 4b, top). Although there is a difference in the FLA10 levels of fla10 and pfl fla10 cells at 0 time, which may be due to the pfl background, it is important to note that a failure to maintain or increase FLA10 levels in pfl fla10 cells at 32°C, as in fla10 cells, is accompanied by a concomitant loss of flagellar structure (i.e., length and rafts; see Fig. 4a and Table II, respectively) and function (i.e., IFT and bead movement; see Table I). In both of the above examples, cells bearing the fla10 allele neither had nor maintained sufficient FLA10 levels at 32°C to ensure normal flagellar structure and function. Therefore, the flagella of cells bearing the fla10 allele may be defective at elevated temperatures not solely because FLA10 is destabilized, but because the elevated temperatures may increase the requirement for FLA10, a requirement that cannot be met in fla10 strains.

**Immunolocalization of FLA10**

The temperature-shift, video-enhanced DIC microscopy
data (Table I) indicated that FLA10 is necessary for two flagellar membrane-associated motilities, IFT and bead movement. To first determine whether any flagellar klp is situated in proximity to the flagellar membrane, and thus in a position to drive IFT and bead movement, immunogold labeling of thin-sections was performed with the LAGSE antibody, which should recognize any klp bearing the conserved LAGSE domain including FLA10. In transverse sections, 30% of the labeling (n = 249 gold particles) was found in the region between the axonomal outer doublet microtubules and the flagellar membrane (Fig. 5, a–d). On occasion, the LAGSE antibody also labeled the rafts between the outer doublet microtubules and flagellar membrane (Fig. 5 c, arrow), although the method of sample preparation for immunogold labeling precluded the routine visualization of the rafts. In addition, the LAGSE antibody labeled the central pair microtubules (Fig. 5, a and d), reflecting, most likely, labeling of the 97- (KLP1; Bernstein et al., 1994) and 110-kD klp (Johnson et al., 1994) that were previously localized to the central pair microtubules.

The affinity-purified FLA10 antibody provided a FLA10-specific probe that only labeled the region between the axonomal outer doublet microtubules and the flagellar membrane (Fig. 5, e–h); label was never found on the central pair microtubules or anywhere else within the core of the axoneme. No flagellar labeling was observed on control sections when the primary antibody was omitted or, in the case of the FLA10 antibody, when the antibody was blocked with the bacterially-expressed FLA10 peptide before incubation with the sections. These data, therefore,

---

Figure 5. EM immunogold localization of FLA10 in wild-type (21gr) flagella using the LAGSE (a–d) or FLA10 antibody (e–h). Note that both antibodies labeled the region between the flagellar membrane and outer doublet microtubules shown in longitudinal (a and e) and transverse sections (b–d and f–h, arrowheads). The FLA10 antibody labeled the region beneath the membrane specifically; whereas, the LAGSE antibody also labeled the klp associated with the central pair microtubules (a and d). Gold particles are 12 nm in diameter.
indicate that FLA10 is situated in proximity to the flagellar membrane and in a position to drive motilities associated with the flagellar membrane.

**Discussion**

By using a temperature-sensitive allele of the *Chlamydomonas* FLA10 gene, we have determined that a flagellar klp is necessary for two motilities that occur in association with the flagellar membrane. Both motilities, IFT and bead movement, were arrested at the restrictive temperature in *pf1* (paralyzed-flagella) cells containing the *fla10* allele. Additionally, we have correlated the presence and position of the IFT particles observed by light microscopy with the presence and position of the rafts observed beneath the flagellar membrane by electron microscopy. A role for FLA10 in IFT and bead movement is also strongly supported by the immunolocalization of FLA10 to the region between the axonemal outer doublet microtubules and the flagellar membrane. Before this study, all of the flagellar klps examined cytologically were localized to the central pair apparatus (Bernstein et al., 1994; Johnson et al., 1994). Of the five or six known flagellar klps, FLA10 is the only klp situated within the flagellum that could drive motility on or beneath the flagellar membrane.

**Number of Flagellar Klps**

The immunoblot data in this report combined with previous reports show that there are at least five flagellar klps in *Chlamydomonas*. On our gradient gels, the 97- and 90-kD polypeptides recognized by the LAGSE antibody co-migrated with the polypeptides recognized by the KLP1 and FLA10 antibodies, respectively. We propose that the polypeptide observed by Fox et al. at 97 kD (Fox et al., 1994) is FLA10 because both FLA10 and the 97-kD polypeptide of Fox et al. are extractable from axonemes with ATP (Fox et al., 1994; Walther et al., 1994), are present in mutants lacking the central pair microtubules (Fox et al., 1994; Johnson et al., 1994; Walther et al., 1994), and are recognized by the pan-klp LAGSE and HIPYR antibodies (Fox et al., 1994; Johnson et al., 1994). The five known flagellar klps in *Chlamydomonas*, therefore, are 125 (unlocalized), 110 (central pair-associated), 110 (central pair-associated), 97 (KLP1; central pair-associated), and 90 kD (FLA10; outer doublet-associated beneath the flagellar membrane).

**Relationship of IFT Particles to Rafts**

Shifting *pf1 fla10* cells to 32°C resulted both in a loss of the IFT particles observed by light microscopy and a significant reduction in the number of rafts between the flagellar membrane and axoneme as observed by electron microscopy. After 90 min at 32°C, no IFT particles were observed with video-enhanced DIC microscopy, but one-third of the rafts remained. A possible explanation for these remaining rafts is the difference in resolution afforded by light and electron microscopy. In comparison to the visibility of the IFT particles in the light microscope, rafts are relatively easy to find and score in thin-sections. Nevertheless, the experiment correlating the spatial relationship between the rafts and IFT particles (Fig. 2) strongly suggests that the prominent IFT particles in the light microscope are the rafts seen beneath the flagellar membrane by electron microscopy.

Although bead movement ceased and the number of rafts decreased at 32°C in the flagella of cells bearing the *fla10* allele, correlative light and electron microscopy data also showed that it is possible to completely arrest bead movement with low calcium/high sodium medium without reducing the number of rafts. This observation is consistent with the possibility that beads may be not carried along the length of the flagellum by the rafts/IFT particles. Bead movement on the reticulopodia of *Allogrornia* and the axopodia of *Echinosphaerium*, likewise, has also been shown to be independent of the movement of large complexes beneath the plasma membrane (Bowser and Bloodgood, 1984). However, it remains possible that beads are moved by rafts/IFT particles. Under particular medium conditions, such as low calcium/high sodium, bead movement may stop because the beads uncouple from the rafts/IFT particles. Along with our earlier observations (Kozminski et al., 1993b), however, that beads move independently of IFT particles and display different rates of movement (discussed further below), the arrest of bead movement without a concomitant loss of rafts more strongly suggests that IFT and bead movement are two different motilities.

**FLA10 Function**

Although a temperature-sensitive mutant allowed us to demonstrate that FLA10 is necessary for IFT and bead movement, we cannot, at present, determine the direct contribution of FLA10 to each of these motilities. Because IFT, but not bead movement, is reduced (i.e., number of IFT particles) at the permissive temperature in *pf1 fla10* cells, it appears that IFT has a greater dependence on normal FLA10 activity than bead movement. At the restrictive temperature, both motilities were affected in the *fla10* mutant. It remains to be shown, however, whether FLA10 directly participates in one or both motilities, if one motility is dependent upon the other, or if FLA10 is involved in an undefined motility that acts upstream of IFT and bead movement. Based on the rates of movement, it seems unlikely that both IFT and bead movement are driven by the same motor. IFT proceeds at approximately 2 μm/s toward the flagellar tip and 3.5 μm/s toward the flagellar base (Kozminski et al., 1993b), whereas bead movement occurs at ~1.1-1.7 μm/s in both directions (Bloodgood, 1977; Kozminski et al., 1993b). In addition, IFT was observed to proceed normally in mutants in which bead movement does not occur or when bead movement is experimentally arrested (Kozminski et al., 1993b). Considering these observations and the fact that IFT is difficult to arrest without inducing deflagellation or cell death (unpublished observations), it is possible that IFT is at the top of a hierarchy of flagellar motilities. IFT, therefore, may be central to the maintenance of flagellar integrity. Disruption of a motor involved in IFT would have pleiotropic effects, resulting not only in the loss of flagellar length and bead movement, but that of other flagellar motilities as well (e.g., flagellar beating).

Because the motor domain of FLA10 is NH2-terminal (Walther et al., 1994), like that of microtubule plus end-directed motors (Goodson et al., 1994), FLA 10 would be...
a suitable motor for transport of materials to the flagellar tip, where the plus ends of all the axonemal microtubules are located (Allen and Borisy, 1974; Binder et al., 1975). Considering that FLA10 appears to be involved with IFT and that IFT particles correlate with rafts beneath the flagellar membrane, FLA10 could be modeled as the motor moving the rafts along the length of the flagellum to the flagellar tip (Fig. 6). FLA10 is certainly in a correct position within the flagellum to drive IFT; that is, FLA10 is localized between the flagellar membrane and the outer doublet microtubules. In a few thin-sections, FLA10 is localized by immunogold labeling to rafts; however, the staining method used in conjunction with the immunogold labeling technique precludes the routine visualization of rafts, thus preventing a conclusive localization of FLA10 to rafts. A potential problem with the proposed model arises from the observation that IFT ceased in both directions along the length of the flagella when fla10 cells were shifted to 32°C. That is, microtubule minus end-directed motility ceased with the temperature-induced perturbation of a microtubule plus end-directed motor. Analogous results, however, can be found in axons, where all the microtubule plus ends are, as in the flagellum, distal to the cell body (Burton and Paige, 1981; Heidemann et al., 1981). In extruded axoplasm, perfusion of anti-kinesin antibodies not only blocked anterograde transport, but retrograde transport as well (Brady et al., 1990). As with axonal transport (Grafstein and Forman, 1980; Vallee et al., 1989), retrograde motility in the flagellum may depend upon anterograde motility for transport to the flagellar tip of the retrograde motor and/or retrograde "cargo" container. At present, the composition of the rafts, cargo, and retrograde motor remains unknown, though we speculate that the retrograde motor may be either a cytoplasmic dynein or a second kinesin with a minus end-directed motor.

**Future Directions**

The use of a temperature sensitive mutant in this study not only helped us to correlate our light and electron microscopy data, but, more importantly, demonstrated the necessity of a flagellar klp for IFT and bead movement. We have found that IFT and bead movement also arrested in fla1 and fla3 cells when those cells were shifted to 32°C for 90 min (unpublished observation). Because all the FLA loci were identified in mutant screens by virtue of the same phenotype (i.e., flagellar instability at 32°C) (Huang et al., 1977; Adams et al., 1982), it is not unusual to expect that the FLA1 and FLA3 genes also encode products required for IFT and bead movement. These genetic products may be in a biochemical pathway that modulates motor function or in a complex with FLA10. Considering the previous analogy between IFT and axonal transport, the latter prospect is exciting, especially in view of the homology between FLA10 (Walther et al., 1994) and KIF5A, a plus end-directed axonal kinesin from mouse that, like its homologue, KRP85/95 from sea urchin (Cole et al., 1993), forms heterotrimeric complexes (Kondo et al., 1994).

The authors would like to thank M. Bernstein, D. Diener, and W. Mages for critical comments and discussion. We also thank M. Bernstein for his assistance with cloning the FLA10 tail sequence. P. Forscher for helpful discussions and the kind use of his microscope, as well as S. Limbach and G. Borisy for sharing their ideas on thermal microscope chambers.

Parts of this work were completed by K. G. Kozminski in partial fulfillment of the requirements for the degree of Doctor of Philosophy (Yale University) and was supported by National Institutes of Health grant GM14462 and National Science Foundation grant 45147 to J. L. Rosenbaum.

Received for publication 21 July 1995 and in revised form 8 September 1995.
