Abstract. Oxygen radicals are important components of metazoan apoptosis. We have found that apoptosis can be induced in the yeast *Saccharomyces cerevisiae* by depletion of glutathione or by low external doses of H2O2. Cycloheximide prevents apoptotic death revealing active participation of the cell. Yeast can also be triggered into apoptosis by a mutation in *CDC48* or by expression of mammalian *bax*. In both cases, we show oxygen radicals to accumulate in the cell, whereas radical depletion or hypoxia prevents apoptosis. These results suggest that the generation of oxygen radicals is a key event in the ancestral apoptotic pathway and offer an explanation for the mechanism of *bax*-induced apoptosis in the absence of any established apoptotic gene in yeast.

Key words: apoptosis • glutathione • oxygen stress • reactive oxygen species • *Saccharomyces cerevisiae*

A POPTOSIS is an active form of cell death crucial for the development and homeostasis of metazoan organisms. In mammals, apoptosis can be induced by various intra- or extracellular stimuli and via several signaling pathways, depending on, for example, cell type, cellular environment, and differentiation state. Virtually every triggering event or component essential for apoptosis in one system has been shown to be dispensable in some other system, e.g., apoptosis in the presence of caspase inhibitors (Xiang et al., 1996; Monney et al., 1998), or in the absence of bax (K nudson et al., 1995; M cC urragh et al., 1997). A apoptosis is characterized by a set of phenotypical alterations such as the exposition of phosphatidylserine on the cell surface (M artin et al., 1995), a characteristic condensation of chromatin to the nuclear envelope (“margination,” Clifford et al., 1996), DNA fragmentation, and the formation of membrane-enclosed cell fragments called apoptotic bodies (K err et al., 1997).

Its obviously altruistic function seemed to limit apoptosis to multicellular organisms. Consistently, in a blast database search of the *Saccharomyces cerevisiae* genome no obvious homologues of any crucial regulator of metazoan apoptosis (members of the bax/bcl-2 family, caspases, A paf-1/CED-4, p53) were detected. However, it has been noted that yeast cells, both *S. cerevisiae* and *Schizosaccharomyces pombe*, can be killed by the expression of a number of proapoptotic mammalian genes, for example, bax (Sato et al., 1994; H anada et al., 1995; G reenhalf et al., 1996) or p53 (B ischoff et al., 1992; N igro et al., 1992).

Our recent observations that a certain *S. cerevisiae cdc48* mutant as well as cells overexpressing bax coordinately show the phenotypic markers of apoptosis, chromatin condensation and fragmentation, DNA breakage, exposure of phosphatidylserine, and the formation of minicells approximating apoptotic bodies, indicates the presence of a basic apoptotic mechanism in yeast (M adeo et al., 1997; L igr et al., 1998). This is in accordance with the observation of chromatin condensation and nuclear fragmentation in *S. pombe* cells dying due to the expression of B ak (I nk et al., 1997) or C ED-4 (J ames et al., 1997). B ax lethality in *S. cerevisiae* can be suppressed by a defect in mitochondrial *F_{0}F_{1}-ATPase* or by the expression of the mammalian gene B l-1. Significantly, B l-1 does not interact directly with B ax, suggesting that it acts on elements already present in yeast (X u and R eed, 1998). Similarly, a mutant form of B cl-X1, an anti-apoptotic B cl-2 family member, has been described, which in the absence of physical interaction can prevent B ax-induced death in yeast (T ao et al., 1997). In mammalian cells, both the inhibition of *F_{0}F_{1}-ATPase* by oligomycin and the expression of B l-1 prevent apoptosis (M atsuyama et al., 1998; X u and R eed, 1998). Obviously, B ax, B ak, or C ED-4 do not simply act as cytotoxic substances in yeast but seem to activate the same or a similar mechanism as in metazoan org-
ganisms. Because of their absence in yeast, this mechanism can not depend on Bax relatives, caspases, or caspase-activated deoxyribonuclease.

The observation of cell death accompanied by apoptosis-like features in yeast suggests that apoptosis developed before the evolutionary separation between fungi and metazoans. Elements of the pathway conserved in yeast as well as animals should therefore belong to a basic, evolutionarily old mechanism. Yeast should be useful to trace the roots of apoptosis and solve some of the complications and apparent contradictions inherent to the various models of apoptosis.

Reactive oxygen species (ROS), are formed in any organism exposed to molecular oxygen appear to be crucial players in apoptosis (Hibbili et al., 1995). ROS or H$_2$O$_2$ can act as primary triggers of apoptosis (Hockenbery et al., 1993; K ane et al., 1993; G reenlund et al., 1995; S latier et al., 1995). The anti-apoptotic effect of Bcl-2 appears to be at least partly due to its antioxidant properties (K ane et al., 1993). In addition, oxygen radicals have been shown to act at a late step of the apoptotic pathway in certain neuronal cells, downstream of the effects of bax or caspases (Schulz et al., 1997).

We present proof that ROS accumulate in yeast cells after induction of apoptotic death by various stimuli, and show them to be necessary and sufficient to induce an apoptotic phenotype in yeast. We suggest that the formation of ROS is a key event in the evolutionary original apoptotic mechanism.

Materials and Methods

Strains and Plasmids

S. cerevisiae strain KFY 437 (MAT a cdc48::URA3 his4-619 leu2-3,112 ura3-52 YEp52/cdc48GSG::mutating mutant allele cdc48GSG:: on vector YEp52), and the corresponding control strain KFY 417 (MAT a cdc48::URA3 his4-619 leu2-3,112 ura3-52 YEp52/CDC48) with a wild-type CDC48 on YEp52 have been described (M adeo et al., 1997). Strain YPH98sh1 was constructed from yeast wild-type YPH98 (MAT a ura3-52 lys2-801 ade2-101 leu2-3,112 trpl-1; Sikorski and H ieter, 1989) by deletion of the complete GSH1 reading frame (B rendel et al., 1998). Cell division cycle mutants used as controls were H artwell (1973) strains L H370 (cdc2)$^0$ and L H12201 (cdc31)$^0$, and £4-15 (cdc48; M oir et al., 1982).

Plasmids pSD10.a-Bax and pSD10.a-Bcl-X were constructed by replacing the URA3 marker of plasmid pSD10.a-B-cX by L E U2. Strain WCG4 (MAT a his3-11 ura3-52 leu2-3,112) was transformed with plasmid pSD10.a-Bax (strain WCG 4bax), or with both pSD10.a-Bax and plX009 (strain WCG4bax/bcl-X), or with vector pRS316 as a control.

YPD contained 1% yeast extract (Difco), 2% Bacto peptone (Difco), and 4% glucose. Synthetic complete medium (SC) consisted of 0.67% yeast nitrogen base (Difco) and 2% glucose (SCD) or 2% galactose (SCGAl) supplemented with amino acids and nucleotide bases. Strains KFY 437 and KFY 417 were pregrown on YEP plates with 4% galactose and incubated in liquid YEPD. WCG4bax, WCG4bax/bcl-X, and the vector control strain were pregrown in synthetic medium with 2% glucose to a cell density of about 0.5 x 10$^6$ cm$^{-1}$. To induce the expression of Bax or Bcl-X, cells were washed 3x and resuspended in synthetic medium with 2% galactose.

For growth under anaerobic conditions, strains were incubated in 100 ml culture medium in wash bottles under flow of N$_2$ (M esser Griesheim GmbH) at 100 ml/min. Viability was determined as the portion of cell forming visible colonies on YEPD plates after 3 d at 28°C.

Test for Apoptotic Markers

Electron microscopy, annexin V labeling, and DAPI staining were performed as described previously (M adeo et al., 1997). For the Tdt-mediated dUTP nick end labeling (TUNEL) test, cells were prepared as described (M adeo et al., 1997), and the DNA ends were labeled using the In Situ Cell Death Detection Kit, POD (Boehringer Mannheim). Yeast cells were fixed with 3.7% formaldehyde, digested with lyticase, and applied to a polylysine-coated slide as described for immunofluorescence (A dams and P riggle, 1984). The slides were rinsed with PBS and incubated with 0.3% H$_2$O$_2$ in methanol for 30 min at room temperature to block endogenous peroxidases. The slides were rinsed with PBS, incubated in permeabilization solution (0.1% Triton X-100 and 0.1% sodium citrate) for 2 min on ice, rinsed twice with PBS, incubated with 10 μl TUNEL reaction mixture (terminal deoxynucleotidyl transferase 200 U/ml, FITC-labeled dUTP 10 mM, 25 mM Tris-HCl, 200 mM sodium cacodylate, 5 mM cobalt chloride; Boehringer Mannheim) for 60 min at 37°C, and then rinsed 3x with PBS. For the detection of peroxidase, cells were incubated with 10 μl Converter-POD (anti-FITC antibody, Fab fragment from sheep, conjugated with horseradish peroxidase) for 30 min at 37°C, rinsed 3x with PBS, and then stained with DAB-substrate solution (Boehringer Mannheim) for 10 min at room temperature. A coverslip was mounted with a drop of K aiser’s glycerol gelatin (M erck). A staining intensity varies, only samples from the same slide were compared.

Free intracellular radicals were detected with dihydroorhodamine 123, dichlorodihydrofluorescin diacetate (dichlorofluorescin diacetate), or dichrohydrothidium (hydroethidine; Sigma Chemical Co.). Dihydrodorhodamine 123 was added ad-5 μg per ml of cell culture from a 2.5 mg/ml stock solution in ethanol and cells were viewed without further processing through a rhodamine optical filter after a 2-h incubation. Dichlorodihydrofluorescin diacetate was added ad-10 μg per ml of cell culture from a 2.5 mg/ml stock solution in ethanol and cells were viewed through a fluorescein optical filter after a 2-h incubation. Dihydrodorhodamine was added ad-5 μg per ml of cell culture from a 5 mg/ml aqueous stock solution and cells were viewed through a rhodamine optical filter after a 10-min incubation. For flow cytometric analysis, cells were incubated with dihydrorhodamine 123 for 2 h and analyzed using a FACSCalibur (Becton Dickinson) at low flow rate with excitation and emission settings of 488 and 525-550 nm (filter FL1, respectively).

Free spin trap reagents N-tetra-butyl-α-phenylhydrazine (PBN; Sigma-Aldrich) and 3,3,5,5-tetramethyl-pyrroline N-oxide (TEMPO; Sigma-Aldrich) were added directly to the cell cultures at 10 μg/ml and incubated 200 min at 30°C with shaking. 100 μl aliquots were spotted onto glass fiber filters and incubated in 10% TCA for 15 min in a boiling water bath. Filters were washed twice with 5% TCA, twice with ethanol and once with methanol, dried and counted with 5 ml Ultima Gold scintillation cocktail (Packard BioScience B.V.).

Results

H$_2$O$_2$ Induces an Apoptotic Phenotype in Wild-type S. cerevisiae

Exposure to H$_2$O$_2$ triggers apoptosis in numerous mammalian cells. To examine its effect in yeast, various amounts of H$_2$O$_2$ were added to wild-type cultures (strain YPH98) growing exponentially on YEPD. A fter a 200-min
incubation, cells were examined for markers of apoptosis. DNA cleavage was assayed using the TUNEL test (Gavrieli et al., 1992; Gorczyca et al., 1993), chromatin was visualized by fluorescence microscopy after DAPI staining as well as by electron microscopy.

We found that low concentrations of H$_2$O$_2$ result in a TUNEL-positive phenotype, which vanishes at higher concentrations. Incubation with 3 mM H$_2$O$_2$ produces a strongly TUNEL-positive phenotype (intense black nuclear stain) in 70% of the cells (Fig. 1 I), indicating massive DNA fragmentation. With 0.3 or 1 mM H$_2$O$_2$, only 20–40% of the cells are stained (Fig. 1 H). TUNEL-positive cells are often remarkably enlarged compared to TUNEL-negative cells from the same batch (Fig. 1 G and H). Cells incubated in the absence of H$_2$O$_2$ showed unstained or only slightly grayish nuclei (Fig. 1 G). Increasing the H$_2$O$_2$ concentration above 5 mM did not intensify the TUNEL reaction. Instead, with 15 mM H$_2$O$_2$ the TUNEL staining is even much less intense and occurs in fewer cells than with 3 mM H$_2$O$_2$ (Fig. 1 J). Incubation with 180 mM H$_2$O$_2$ results in no detectable TUNEL staining (Fig. 1 K). To demonstrate that the DNA fragmentation is not a result of cell necrosis, membrane integrity was tested by incubating an aliquot of the protoplasts used for TUNEL staining with 23 μg/ml propidium iodide. Only 3–5% of the protoplasts from cultures treated with 0–5 mM H$_2$O$_2$ are stained (not shown). In cultures incubated with 180 mM H$_2$O$_2$, ~80% of the protoplasts are stained with propidium iodide, indicating the loss of plasma membrane integrity. Cells from stationary cultures tolerate higher concentrations of H$_2$O$_2$. A 30 min incubation with 5 mM H$_2$O$_2$ or less, no TUNEL staining is observed (not shown). On the other hand, incubation with 180 mM H$_2$O$_2$ results in a strong TUNEL staining (Fig. 1 I).

A nalysis of isolated chromosomal DNA from H$_2$O$_2$ cells by agarose electrophoresis showed only a smear at low molecular weights, but not the DNA ladder pattern (not shown) that is found in many apoptotic systems as the result of DNA cleavage between nucleosomes. This confirms our result with the cdc48 mutant showing an apoptotic phenotype (Madeo et al., 1997) and is probably caused by the S. cerevisiae chromatin structure with little or no linker DNA between the nucleosomes (Lowary and Widom, 1989). In addition, apoptosis without the occurrence of a DNA ladder has been described for several metazoan cell types (Oberhammer et al., 1993).

DAPI staining of cells incubated with 3 mM H$_2$O$_2$ shows chromatin fragments arranged in a half-ring (Fig. 1 D) or distributed nuclear fragments (Fig. 1 A, B, and E) in 10–50% of the cells. In some cells, nuclei seem to degenerate, showing protruding tubes (Fig. 1 C). In untreated cultures, all nuclei appear as single round spots in the cells. In contrast to nuclei or most nuclear fragments, mitochondria are predominantly located near the periphery of the cells and appear as dots of far less intensity and size (Fig. 1 D).

Electron microscopic investigation of cells incubated with 3 mM H$_2$O$_2$ revealed extensive chromatin condensation along the nuclear envelope typical for apoptosis (migration, Fig. 2, D and E), cells containing multiple nuclear fragments (Fig. 2 E), as well as tubular structures protruding from the nucleus (Fig. 2 F) that probably correspond to the tubular structures observed in DAPI-stained cells (Fig. 1 C). Some condensation is already visible after 30 min H$_2$O$_2$ treatment (Fig. 2 A) increasing gradually with time (Fig. 2 B and C). Nuclei of untreated cells are homogeneous in shape and density (Fig. 2 I). In addition, some cells show tiny vesicles on the outer side of the plasma membrane (Fig. 2, D and F). This could be an equivalent of membrane blebbing that is a characteristic marker of apoptosis and has not been observed in yeast cells before. At higher concentrations of H$_2$O$_2$, most intracellular structures are destroyed (Fig. 2 H), indicating necrotic cell death. This corresponds to the diminished TUNEL reaction in these cultures (Fig. 1 K).

![Figure 1](image)

Figure 1. H$_2$O$_2$ induces an apoptotic phenotype in yeast. DAPI-stained wild-type yeast after incubation for 200 min without (F) and with 3 mM H$_2$O$_2$ (A–E) in YEPD. TUNEL reaction after 200 min treatment of exponentially growing cells with 0 mM (G), 1 mM (H), 3 mM (I), 15 mM (J), and 180 mM H$_2$O$_2$ (K), stationary cells treated with 180 mM H$_2$O$_2$ (L), exponentially growing cells treated with 3 mM H$_2$O$_2$ plus 15 μg/ml cycloheximide (M), and exponentially growing cells treated with 15 μg/ml cycloheximide for 230 min (N). Survival (colony formation on YEPD plates, 100% corresponds to the number of plated cells) of wild-type yeast incubated with H$_2$O$_2$ in the absence (black) or presence (red) of 15 μg/ml cycloheximide for 200 min (O). Results were averaged from three experiments. Bars: 5 μm (A–F, G–N).
Cycloheximide Prevents the Apoptotic Effects of H$_2$O$_2$ on Yeast Cells and Improves the Survival Rate

A apoptosis needs participation of the cell and can be prevented in many cell types by the inhibition of protein synthesis (Hiraoka et al., 1997; Sánchez et al., 1997). To address the question whether the H$_2$O$_2$-induced DNA breakage, chromatin condensation, and cell death are the result of basic radical chemistry or depend on participation of the cellular metabolism, we investigated the effect of cycloheximide on H$_2$O$_2$-treated yeast cells.

To establish which concentration of cycloheximide is sufficient for complete inhibition of protein synthesis, incorporation of labeled leucine into TCA precipitable material was determined. 5 μg/ml cycloheximide reduced leucine incorporation to 23% of the untreated control, 15 μg/ml cycloheximide, or higher concentrations reduced the incorporation to <8% of the untreated control.

Exponentially growing wild-type cultures were preincubated with 15 μg/ml cycloheximide for 30 min. After adding 3 mM H$_2$O$_2$, cultures were incubated for another 200 min. DNA fragmentation was visualized by TUNEL staining (Fig. 1 M). The resulting TUNEL assay stain is only slightly more intense than in untreated controls (Fig. 1 G) and far weaker than in cells treated with 3 mM H$_2$O$_2$ in the absence of cycloheximide (Fig. 1 I). Incubation only with cycloheximide for 230 min (Fig. 1 N) results in approximately the same enhancement of TUNEL staining as the combination of cycloheximide and 3 mM H$_2$O$_2$. This mi-

Figure 2. Low concentrations of H$_2$O$_2$ and glutathione depletion induce chromatin condensation and margination in S. cerevisiae. Electron micrographs of exponentially grown wild-type strain YPH98 treated with 3 mM H$_2$O$_2$ for 30 min (A), 60 min (B), 120 min (C), or 200 min (D-F), with 3 mM H$_2$O$_2$ plus 15 μg/ml cycloheximide for 200 min (G, nucleolus visible), with 180 mM H$_2$O$_2$ for 200 min (H), untreated control (I), and of gsh1 deletion strain YPH98gsh1 grown on glutathione-free synthetic medium for 3 d (J and K). N, nucleus; V, vacuole; chromatin condensation is marked by arrows, extracellular vesicles (blebs) are marked by arrowheads. Bar, 1 μm.
nor increase in DNA fragmentation compared to untreated controls could be due to a reduction of DNA repair as a result of the inhibited protein synthesis.

Under the electron microscope, neither chromatin condensation, margination, nor nuclear fragmentation is detected in cells incubated with H2O2 in the presence of cycloheximide. However, numerous cells show vacuoles accumulating autophagic bodies, increased intracellular vacuolization, or misformed nuclei indicating necrotic damage (Fig. 2 G).

To investigate the effect of cycloheximide on yeast cell survival during oxygen stress, we incubated exponentially growing wild-type cultures with 15 μg/ml cycloheximide for 30 min, added various concentrations of H2O2, and incubated the cultures for another 200 min. Survival was determined as the portion of cells forming colonies after 3 d of incubation on YEPD plates. Cycloheximide considerably increased the cell survival rate in the range of 0.03 to 0.3 mM H2O2 (Fig. 1 O).

To investigate whether cycloheximide affects intracellular glutathione concentration by the inhibition of protein synthesis, the level of intracellular glutathione was determined as described (Schmidt et al., 1996). Untreated wild-type cells contained 1.55 μM glutathione per gram of wet twice-washed cells. Incubation with 15 μg/ml cycloheximide for 230 min increased the glutathione level to 140% of the control. The increase is probably caused by accumulation of cysteine. However, even an increase of the glutathione level to 250% of the wild-type level by overexpression of cysteine. The level of intracellular glutathione was determined as the portion of cells forming colonies after 3 d of incubation on YEPD plates. Cycloheximide considerably increased the cell survival rate in the range of 0.03 to 0.3 mM H2O2 (Fig. 1 O).

A Yeast Strain Lacking Glutathione Exhibits the Characteristic Markers of Apoptosis

Glutathione plays a major role in the protection against ROS. Strain YPH98gsh1 lacks glutathione due to a deletion of the GSH1 gene coding for γ-glutamylcysteine synthetase. It grows on YEPD due to the significant amounts of glutathione contained in the yeast extract, as well as on synthetic media supplemented with glutathione, but dies after 3 d on glutathione-free media (Brendel et al., 1998).

Strain YPH98gsh1 and the isogenic wild-type strain YPH98 were transferred from YEPD plates to glutathione-free synthetic medium plates and incubated for 3 d. Cells were examined for the phenotypic markers of apoptosis: DNA breakage, chromatin condensation and margination, and the exposure of phosphatidylserine.

The deletion strain shows strong staining (black nuclei) with the TUNEL test indicating massive DNA fragmentation in >80% of the cells (Fig. 3 G), while the control strain shows no TUNEL staining (Fig. 3 H). When the deletion strain is grown on YE PD or on synthetic medium supplemented with 20 μg/ml glutathione, nuclear staining is not observed with the TUNEL assay (not shown).

An aliquot of the protoplasts used for TUNEL staining was also tested for membrane integrity by incubation with 23 μg/ml propidium iodide. 10–20% of the protoplasts of both wild-type and glutathione deficient strain are stained (data not shown), confirming that the majority of the cells is intact and that the DNA fragmentation is not a result of cell necrosis.

The deletion strain exhibits an enhanced sensitivity towards H2O2. Incubation with 0.1 mM H2O2 induces a strong TUNEL reaction, as well as condensation and fragmentation of chromatin, whereas little or no TUNEL staining is observed after incubation with 3 mM H2O2 or higher concentrations (not shown).

A analysis of isolated chromosomal DNA from the deletion strain by agarose electrophoresis showed no indication of DNA laddering (not shown).

DAPI staining of the deletion strain shows a strong chromatin condensation with fragments arranged in a ring, a half-ring (Fig. 3, A and C), or as several randomly distributed nuclear fragments (Fig. 3 E). Electron micrographs show intense chromatin margination (Fig. 2 J) and fragmentation of the nucleus (Fig. 2 K). In cells of the deletion strain grown on YEPD medium or on synthetic medium supplemented with 20 μg/ml glutathione, no chromatin condensation or fragmentation occurs (not shown).

In mammalian cells, phosphatidylserine exposure at the outer leaflet of the cytoplasmic membrane is an early marker of apoptosis (Martin et al., 1995). The exposure can be detected with annexin V that specifically binds phosphatidylserine in the presence of Ca2+. Like mammalian cells, S. cerevisiae has an asymmetric distribution of phospholipids within the cytoplasmic membrane with 90% of the phosphatidylserine on the cytoplasmic side of the membrane (Cerbón and Calderón, 1991). We have recently described the exposure of phosphatidylserine in a yeast CDC48 mutant showing characteristics of apoptotic cells (Madeo et al., 1997).

Spheroplasts of the GSH1 deletion strain and the isogenic control strain grown on glutathione-free synthetic medium for 3 d were examined for exposure of phosphatidylserine by incubation with FITC-labeled annexin V and for membrane integrity by incubation with propidium iodide. Approximately 20% of the protoplasts, both wild-type and mutant strain, take up propidium iodide indicating membrane damage. These protoplasts often exhibit annexin V staining of the whole cell. More than 15% of the protoplasts from the deletion strain show a strong fluorescence around the circumference of the cell (Fig. 3, I–K) of which none stain with propidium iodide, demonstrating that phosphatidylserine is indeed exposed at the outer layer of the cytoplasmic membrane (Fig. 3, K and L). All intact protoplasts of the isogenic control show little or no FITC staining in the cell lumen (Fig. 3 M). When the deletion strain was grown on YE PD or on synthetic medium supplemented with 20 μg/ml glutathione, no annexin V fluorescence is visible either (not shown).

The Apoptotic Phenotype of cdc48S565G Mutant Strain KFY437 Is Triggered by an Accumulation of ROS

To investigate whether oxygen stress is involved in other apoptotic scenarios described in S. cerevisiae, we tested apoptotic mutant strain KFY437 for the occurrence of ox-
Figure 3. A yeast lacking glutathione exhibits the typical markers of apoptosis, nuclear breakage, DNA fragmentation, and exposition of phosphatidylserine. gsh1 mutant (A, C, E) and wild-type control (F shows two cells) grown for 3 d on synthetic medium stained with DAPI; B and D are phase contrast pictures corresponding to A and C. TUNEL test of gsh1 mutant (G) and wild-type control (H) grown for 3 d on synthetic medium; L shows the propidium iodide staining corresponding to K. Bars: 10 μm (A–F, I–M); 10 μm (G and H).

Oxygen radicals. Strain KFY437 expresses cdc48S56S5, a mutated allele of CDC48 responsible for the homotypic fusion of ER-derived vesicles, and spontaneously develops an apoptotic phenotype during exponential growth at 28°C while other conditional alleles of CDC48 result in cell death at the restrictive temperature without exhibiting any of these morphological markers (Madeo et al., 1997).

Strain KFY437 was tested for the production of ROS during apoptosis by incubation with dihydrodorhodamine 123. This substance accumulates in the cell and is oxidized to the fluorescent chromophore rhodamine 123 by ROS (Schulz et al., 1996).

Strain KFY437 growing exponentially on YEPD was incubated with 10 μM dihydrodorhodamine 123 for 2 h at 28°C. More than 50% of the cells show a rhodamine 123 fluorescence (Fig. 4 B). Most of the cells of the corresponding wild-type strain show no fluorescence, appearing dark against the faint background fluorescence. Marginal fluorescence occurs in <1% of the cells (Fig. 4 A). Incubation for 2 h with 10 μM dichlorodihydrofluorescein diacetate, which is deacylated to dichlorodihydrofluorescein and oxidized by ROS to fluorescent dichlorofluorescein (Hockenbery et al., 1993), or with 5 μM dihydroethidium for 10 min, which is oxidized specifically by superoxide ions to the fluorescent ethidium (Budd et al., 1997), gave similar results (not shown). Flow cytometric analysis of dichlorodihydrofluoruecin 123-stained cells confirms that strain KFY437 accumulates oxygen radicals. A majority of the mutants cells show an increased signal (Fig. 4 V), while all wild-type cells display a low fluorescence (Fig. 4 U).

We found that elevated temperature (37°C) induces apoptotic cell death in most cells of strain KFY437. After 4 h at 37°C, >80% of the KFY437 cells show a strong TUNEL reaction as well as condensed and fragmented chromatin. The elevated temperature induces a higher intensity of TUNEL staining as compared to cells grown at 28°C (Fig. 5, B and D). When strain KFY437 is incubated at 37°C for 4 h, more than 80% of the cells show a strong rhodamine 123 fluorescence (Fig. 4 D) of a significantly higher intensity than at 28°C. The majority of cells also show intense fluorescence after incubation with dichlorodihydrofluorescein (Fig. 4 N) or dihydroethidium (Fig. 4 P). The isogenic wild-type strain shows no increased fluorescence at 37°C with either dye (Fig. 4, M and O).

To verify that the accumulation of ROS is not an effect of any cell cycle arrest, temperature sensitive mutants in cell division cycle genes were arrested at 37°C for 4 h, incubated with dihydrodorhodamine 123 and tested for fluorescence. Neither a non-apoptotic allele of CDC48 (cdc48-3), nor mutants in cdc2 (arresting as large-budded cells like cdc48 mutants) or cdc31 (arresting with an abnormal spindle-like cdc48 mutants) show an increase of intracellular fluorescence (not shown).

Oxygen Radical Scavengers and Anaerobic Conditions Suppress Temperature Sensitivity and DNA Fragmentation of Apoptotic cdc48 Mutant KFY437

To discriminate whether the accumulation of ROS is just a byproduct of the induction of apoptosis in the cdc48 mutant or whether it is essential for the process, oxygen radicals were scavenged with free radical spin traps (Knecht and Mason, 1993). Strain KFY437 and the corresponding wild-type strain KFY417 were grown on YEPD with shaking at 28°C and then incubated with various concentrations of PBN or TEMPO for 4 h at 37°C. To evaluate effects on survival, cell viability was determined as the number of colonies formed after plating a defined number of cells. A aliquots of the same sample were used for TUNEL reaction and electron microscopic investigation. 5 mM PBN (Fig. 5 E) and 0.5 mM TEMPO suppress TUNEL staining dramatically, whereas 0.5 mM PBN and 5 mM TEMPO have less effect (not shown). Electron microscopy shows that the intense chromatin margination of strain KFY437 at 37°C (Fig. 5 J) is prevented almost
completely by 5 mM PBN (Fig. 5 K). These observations correspond to the protective effect of the spin traps on cell viability at 37°C, which is strongest with 0.5 mM TMPO or 5 mM PBN. Viability of the wild-type control is inhibited by the spin trap substances, indicating a certain cytotoxicity (Fig. 6 A). At some concentrations of TMPO, proliferation of the control strain is even lower than that of the apoptotic strain. This might be due to
neutralization of radicals and spin traps in the apoptotic cdc48 mutant.

A similar protective effect was observed after incubation in an anaerobic environment. Mutant cultures and controls were incubated in a nitrogen atmosphere at 28°C for 30 min and further incubated in a 37°C waterbath for 4 h under nitrogen. Their viability was tested in a plating assay. While the control was not affected by the anaerobic conditions, the mutant strain showed significant survival after anaerobic conditions (Fig. 6 B). Incubation in a nitrogen atmosphere also prevented accumulation of DNA strand breaks, as shown by TUNEL staining (Fig. 5 F).

**Bax Expression Induces Accumulation of Reactive Oxygen Species in S. cerevisiae**

Expression of bax in S. cerevisiae results in cell death with an apoptotic phenotype that is suppressed by the coexpression of bcl-X<sub>L</sub> (Ligr et al., 1998). To determine whether Bax-induced apoptosis in yeast is also accompanied by oxygen stress, strain WCG4bx carrying a bax gene controlled by the GAL1 promoter was used. Bax expression was induced on galactose medium for 4 h or 13 h. 5 μg/ml dihydrorhodamine were then added and the fluorescence determined after 2 more hours of incubation. After a total of 6 h induction, strain WCG4bx shows little fluorescence (not shown). After 15 h, >80% of WCG4bx cells show an intense rhodamine 123 fluorescence (Fig. 4 E), while the control strain (empty vector) shows no detectable fluorescence (not shown). Coexpression of bcl-X<sub>L</sub> suppresses the bax-induced accumulation of radicals. The strain WCG4bx/bcl-X<sub>L</sub> shows almost no rhodamine 123 fluorescence after 15 h incubation with galactose (Fig. 4 F). Incubation with dichlorodihydrofluorescein diacetate or dihydroethidium gave similar results (not shown). Flow cytometric analysis of dihydrorhodamine 123-stained cells confirms that a majority of bax-expressing cells show an increased signal, while all control cells display a low fluorescence (not shown).

To determine whether spin traps can prevent Bax-triggered cell death WCG4bx and the corresponding wild-type strain (empty vector) were incubated with the free radical spin traps PBN or TMPO at 28°C on galactose media for 15 h. Viability was determined as the portion of colony-forming units. While spin traps have a toxic effect on the control strain, WCG4bx survival is partially restored.
As with the apoptotic cdc48 mutant, 5 mM PBN has the strongest protective effect on WCG4bax (Fig. 6 C). Accordingly, 5 mM PBN prevents DNA strand breakage (Fig. 5 H) and chromatin condensation (Fig. 5 M) occurring in bax-expressing WCG4bax in the absence of spin traps (Fig. 5, G and L).

Anaerobic conditions also strongly reduce cell death and DNA breakage after induction of bax. Strain WCG4bax and the vector control strain were incubated in galactose medium in a nitrogen atmosphere at 28°C for 15 h. Viability of the bax-expressing strain is restored to control levels under these anaerobic conditions (Fig. 6 D). The corresponding TUNEL test shows no indication of strand breaks (Fig. 5 I).

Discussion

In metazoan apoptosis, ROS have been shown to participate in both early and late steps of the regulatory chain. In several apoptotic models, for example in ischemia-induced apoptosis (Maulik et al., 1998), ROS act upstream of bax and caspases. In these models, radical trapping prevents the activation of caspases, and an inhibition of ensuing steps, e.g., with caspase inhibitors, prevents cell death indicating that the radicals act as signal molecules and do not simply cause lethal damage to DNA, lipids or proteins (Harra et al., 1997; Boggs et al., 1998; Tan et al., 1998). However, radicals have also been shown to play a role in the late steps of apoptosis. K⁺ deprivation induces apoptosis in cerebellar granule neurons via an accumulation of ROS. ROS production is prevented by actinomycin D, cycloheximide, and caspase inhibitors Ac-YVAD-CMK, suggesting that ROS act downstream of gene transcription, mRNA translation, and activation of caspases (Schulz et al., 1997, 1996).

Two scenarios connecting yeast with metazoan apoptosis have been described previously. The expression of some metazoan proapoptotic genes (bax, bax, ced-4) results in cell death (Sato et al., 1994; Hanada et al., 1995; Greenhalff et al., 1996; J ames et al., 1997) accompanied by an apoptotic phenotype (Ink et al., 1997; Ligr et al., 1998). The mutant allele cdc48S565G induces the appearance of
The phenomenon that glutathione is actively extruded during apoptosis of human monocytes (Ghibelli et al., 1995) may be a strategy to enhance ROS signaling-induced apoptosis. Some apoptotic pathways retain the usage of ROS in early regulatory steps, other pathways still use it in late steps. In addition, alternative pathways lacking the involvement of ROS developed that cannot be blocked by radical trapping. But even in the case of the ROS-independent apoptotic pathway via CD95 (Hug et al., 1994), the expression of the proapoptotic CD95 ligand is induced by ROS (Hug et al., 1997).

While none of the established apoptotic proteins are encoded in the S. cerevisiae genome, some of them will perform similar functions when expressed in yeast cells. In mammals, one of the effects of Bax expression is a caspase-independent production of ROS (Xiang et al., 1996). Our finding that the expression of Bax protein in yeast also results in an accumulation of ROS that is prevented by the coexpression of Bcl-2, indicates a mechanism for the induction of cell death and apoptotic phenotype by Bax in yeast. An organic ROS are therefore the first regulators of apoptosis found to be shared between yeast and higher animals (Fig. 7). Future research should address whether the mechanism downstream of this signal uses conserved elements.

We thank J. M. Morgan for the gift of Bax and Bcl-2, plasmids, and Dieter Mecke for discussion and support. We acknowledge the support of Jürgen Voigt with radio labeling and of Matthias Rose with FACS® analysis. We are grateful to Harald Taylor for critical reading of the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft.

Received line for publication 1 September 1998 and in revised form 2 April 1999.
