Introduction

Intraflagellar transport (IFT)* (Kozminski et al., 1993) is essential for the assembly and maintenance of sensory cilia in Caenorhabditis, motile cilia in sea urchins and Chlamydomonas, and primary cilia in mice, and is likely to be important in all cilia. During IFT, kinesin-II transports a large protein complex from the cell body to the tip of the flagellum (Morris and Scholey, 1997; Piperno and Mead, 1997; Cole et al., 1998; Orozco et al., 1999; Signor et al., 1999b). These particles are then returned to the cell body by the DHC1b/DHC2 isofrom of cytoplasmic dynein (Pazour et al., 1998, 1999; Porter et al., 1999; Signor et al., 1999a). IFT particles in Chlamydomonas are composed of at least 17 proteins and are thought to carry components needed to build and maintain the ciliary axoneme and membrane (Piperno and Mead, 1997; Cole et al., 1998). The functions of individual IFT particle proteins are not known, but their sequences are conserved among green algae, nematodes, and vertebrates (Cole et al., 1998). Mutations in genes encoding IFT particle proteins prevent ciliary assembly in Chlamydomonas, Caenorhabditis, and mice (Cole et al., 1998; Murcia et al., 2000; Pazour et al., 2000).

Vertebrate photoreceptors are polarized sensory neurons consisting of a photosensitive outer segment (OS) that develops from a nonmotile primary cilium by movement of membrane and phototransduction proteins, such as opsin, into the cilium (Besharse and Horst, 1990). The cilium remains in mature photoreceptors as the sole connecting link between the inner segment (IS) and OS and is presumably the major transport corridor. Mature photoreceptors continue to require transport from the IS to the OS to replace components of the OS that are turned over each day (Young, 1967). It has been estimated that normal turnover in each mammalian OS requires delivery of as many as 2,000 photopigment molecules per minute throughout the life of the cell (Besharse and Horst, 1990). In the larger photoreceptors of amphibians, this rate must be increased by more than an order of magnitude (Besharse and Horst, 1990). In addition to photopigment molecules, phototransduction proteins (Philp et al., 1987; Whelan and McGinnis, 1988) and phos-
pholipid components of the discs (Anderson et al., 1980) also turn over rapidly. Although disruption of intersegmental transport results in photoreceptor degeneration and blindness (Li et al., 1996; Hagstrom et al., 1999; Clarke et al., 2000), the transport mechanisms have not been identified.

IFT has been proposed as a connecting cilia transport mechanism (Rosenbaum et al., 1999). In support of this idea, Marszalek et al. (2000) showed that a conditional knockout of KIF3A, which is a subunit of the anterograde IFT motor, leads to retinal degeneration. However, KIF3A-containing motors are believed to be involved in other cellular processes, including neuronal transport, melanosome movement, and secretory pathway transport (Marszalek and Goldstein, 2000). To more directly test the role of IFT in connecting cilia transport, we here investigate the distribution of IFT particle proteins in vertebrate retinas, and examine the effect of a mutation in an IFT particle subunit gene on the mouse retina. We show that mouse homologues of four Chlamydomonas IFT protein particles are localized to the connecting cilia, and mice with a mutation in the Tg737/IFT88 subunit of the IFT particle form abnormal OSs followed by progressive photoreceptor degeneration. These data strongly suggest that IFT is an important transport mechanism in vertebrate photoreceptors and raise the possibility that defects in IFT may cause some forms of human blindness.

Results

Vertebrate IFT particle proteins

The Chlamydomonas IFT particle is composed of ~17 proteins. We have used peptide sequence obtained from purified particle proteins to clone and sequence the Chlamydomonas genes, which were then used to identify mammalian homologues in Genbank/EMBL/DDBJ. Mammalian homologues of IFT88, IFT57, IFT52, and IFT20 were chosen for further study in this work. Chlamydomonas IFT88 is 42% identical (BLAST E = 1e – 142) to a mouse protein, called Tg737, that is required for assembly of primary cilia in the mouse kidney (Pazour et al., 2000) and node (Murcia et al., 2000). The Caenorhabditis elegans homologue of IFT88, OSM-5, is required for sensory cilium formation and moves within the sensory cilium (Haycraft et al., 2001; Qin et al., 2001). Chlamydomonas IFT57 is 38% identical (BLAST E = 3e – 67) to a mouse coiled-coil protein (unpublished data). Chlamydomonas IFT52 is 49% identical (BLAST E = 1e – 87) to a rodent protein called NGD5 and a C. elegans protein called OSM-6 (Cole et al., 1998; Deane et al., 2001). The function of NGD5 is unknown, but its expression is down-regulated by exposing cultured cells to opioids (Wick et al., 1995). OSM-6 is required for assembly of sensory cilia in nematodes (Collet et al., 1998). Chlamydomonas IFT20 is 32% identical (BLAST E = 4e – 15) to a small hypothetical protein in mouse as well as ESTs from humans and other vertebrate species.

IFT proteins in mouse testis and retina

Chlamydomonas IFT particles sediment as 17S complexes (Cole et al., 1998). To determine if the four mammalian homologues also are present in a large complex, we fractionated cytoplasmic extracts of mouse testis on sucrose gradients and examined the distribution of the IFT particle proteins by Western blotting (Fig. 1, a and b). Testis was chosen because the IFT proteins are much more abundant in this tissue than in any other, including retina. The four mammalian IFT proteins cosedimented at 17S, indicating that, like their algal homologues, they are part of a large complex. These data provide the first direct evidence of an IFT particle in a mammalian system and demonstrate the utility of the affinity-purified antibodies to IFT proteins.

IFT proteins were more difficult to detect in the retina than in the testis. Westerns of whole retinal protein extracts with the IFT88 antibody showed that wild-type retina contained an ~90-kD protein that was greatly reduced in Tg737 mutated retina (Fig. 1 c). Several additional bands were detected with this antibody. It is likely that these are unrelated cross-reactive proteins, as their level did not change in the Tg737 mutant mice. The IFT88 antibody was used to stain mutant and wild-type mouse retinas to see if differences could be detected. The IFT88 antibody (Fig. 1 d, green) strongly labeled the IS of the wild-type retina without significantly labeling this segment in the mutant. The staining was distinctly granular in nature and the brightest foci were associated with the ends of photoreceptor connecting cilia (Fig. 1 d, red). Connecting cilia could be detected in
the mutant retinas but green foci were not associated with them, indicating that this staining is due to the IFT88 protein, and not one of the cross-reactive proteins.

Localization of IFT proteins to basal body and connecting cilium in bovine retina

The low abundance of IFT proteins in the retina and the small size of the mouse retina made biochemical studies difficult. To circumvent this problem, we used bovine retina. Bovine retina is often used as a biochemical system for photoreceptor research, and techniques are available for making a detergent-extracted photoreceptor cytoskeleton (DEPC) fraction that is enriched in connecting cilia (Horst et al., 1987). Furthermore, the K26 monoclonal antibody, which binds specifically to and is an excellent marker for the photoreceptor connecting cillum (Horst et al., 1990), works only in bovine photoreceptors.

Affinity-purified antibodies to IFT20, IFT52, IFT57, and IFT88 did not readily detect proteins of the expected sizes in whole cell extracts of bovine retina (unpublished data). However, these antibodies strongly detected single bands of ~16, 52, 57, and 90 kD, respectively, in the DEPC fraction (Fig. 2, a and b), suggesting that these proteins are associated with the photoreceptor connecting cilium. The retina is composed of multiple cell types, and it is likely that the failure to detect IFT proteins in whole retina is because these proteins are not abundant in the nonphotoreceptor cells. If the IFT proteins are concentrated at the connecting cillum, as the mouse result suggested, the DEPC would be greatly enriched for these proteins, as the purification of the DEPC would remove the nonphotoreceptor cells as well as most of the proteins of the photoreceptor cells.

Immunocytochemical analysis confirmed that IFT20, IFT52, IFT57, and IFT88 are most abundant in the IS of bovine photoreceptors (Fig. 2 c). The signal in the IS was distinctly granular in appearance, particularly at the boundary between the IS and OS layers where the connecting cillum are located. Much weaker immunoreactivity was also seen in the outer plexiform layer, which contains the synaptic terminals of photoreceptors (Muresan et al., 1999) raise the possibility that IFT proteins may have functions in photoreceptor synaptic terminals.

Double label immunocytochemistry with a monoclonal antibody (K26) that recognizes an unknown connecting cillum-specific epitope (Horst et al., 1990) demonstrated that all four IFT proteins are associated with the cilium and basal body in situ (Fig. 2, d–j). The K26 antibody uniquely stained the connecting cillum at the bases of the OSs, which were identified with antibodies to rod opsin (Fig. 2 d). In contrast, an-
tibodies to acetylated α-tubulin labeled microtubules of the IS and the ciliary axoneme (Fig. 2, e and f). Overlap of K26 (red) and acetylated α-tubulin (green) antibodies in the connecting cilium resulted in a yellow to orange color, and demonstrated that axonemal microtubules extend distally beyond the connecting cilium into the OS. Antibodies to IFT20, IFT52, IFT57, and IFT88 labeled both the proximal (IS) and distal (OS) ends of the connecting cilia in most photoreceptors (Fig. 2, g–j). Frequent yellow to orange coloration of the connecting cilium was indicative of overlap of the two labels (Fig. 2, i and j; red, K26; green, anti-IFT antibody). Triple-labeled images revealed a similar pattern (Fig. 2, k–m) in which IFT57 (blue) is associated with microtubules (green, acetylated α-tubulin) at both ends of the connecting cilium (red, K26) in most photoreceptors.

**Effect of the IFT88/Tg737 mutant allele on photoreceptor cells**

To directly test the role of IFT in photoreceptor cells, we examined retinas from mice homozygous for an insertional mutation in the Tg737 gene. The Tg737 allele was generated by integration of DNA into one of the exons but did not affect the coding potential of the adjacent exons. This reduces, but does not completely abolish, the ability of this gene to produce protein (Moyer et al., 1994; Taulman et al., 2001; unpublished data). Tg737 encodes IFT88 (Pazour et al., 2000), also called “polaris” (Murcia et al., 2000). Mutations in this gene cause ciliary assembly defects in *Chlamydomonas, C. elegans,* and the mouse kidney and embryonic node (Murcia et al., 2000; Pazour et al., 2000; Haycraft et al., 2001; Qin et al., 2001). The original Tg737 insertional mutant mouse line is homozygous for the autosomal recessive *Pdeb*<sup>rd1</sup> mutation that causes rapid degeneration of photoreceptors before postnatal day (p) 20 (Carter-Dawson et al., 1978; Bowes et al., 1990; Pittler and Baehr, 1991). Because the effects of the *Pdeb*<sup>rd1</sup> mutation would mask effects of the Tg737 mutation, mice were bred to eliminate one or both of the *Pdeb*<sup>rd1</sup> mutant alleles. Tg737 mutant homozygotes that were both heterozygous and homozygous wild type for *Pdeb*<sup>rd</sup> were studied at p10, p21, p45, p77, and p84.

Mouse OSs normally begin to develop around p4, achieving adult proportions with well-aligned disc membranes by p20 (LaVail, 1973). In Tg737 mutant mice, a normal number of photoreceptors form, but OS structure is abnormal at all time points examined. At p10, the OSs in Tg737 mutant mice are greatly reduced in size and difficult to see by light microscopy (Fig. 3, A and B). At the EM level, the mutant OSs are disorganized. In wild-type animals, most discs are well aligned in a stacked array (Fig. 3, C and D), but this is rarely seen in Tg737 mutant OSs (Fig. 3, E and F). Instead, discs often form parallel with, rather than perpendicular to, the connecting cilium, and in some OSs the disc membranes are broken into small segments (Fig. 3 E). Another frequently seen anomaly is the development of the OS from the lateral side of the IS and partial intrusion of the OS into the IS (Fig. 3 F). This anomaly suggests breakdown of the mechanism that correctly positions the basal body, because in wild-type mice OSs always develop from the apical (distal) end of the IS.

At p21, Tg737 mutant retinas still have near normal numbers of photoreceptor nuclei in the outer nuclear layer (ONL) (Fig. 4, a–d). However, the mutant OSs are not as uniform in size or alignment and appear to be less abundant (Fig. 4, a and b). OSs of both wild type and mutant show abundant opsin immunoreactivity (Fig. 4, c and d). In contrast to wild type, opsin immunoreactivity is observed in the ISs and cell bodies of Tg737 mutant photoreceptors (Fig. 4, c and d, and Fig. 7). At the EM level (Fig. 4, e and f), the mutant photoreceptors are less uniformly aligned, less densely packed, and contain broader, less organized discs than the wild-type photoreceptors. In addi-
tion, the extracellular space of the mutant retinas is filled with vesicular material (see below).

By p45, the ONL is reduced significantly in thickness in Tg737 mutant mice compared with littermate controls (Fig. 5, A and B). Pycnotic nuclei in the mutant ONL indicate that the photoreceptor cells are dying by apoptosis. Loss of photoreceptors, measured by reduction of the ONL, reaches 60–80% \( (n = 6 \text{ retinas}) \) by p77 (Fig. 5 C). In one mutant retina examined at p84, only one layer of photoreceptor nuclei could be seen (Fig. 5 D). Thus, the Tg737 mutation causes progressive photoreceptor degeneration with major loss of cells by p77. Early development of a near normal complement of photoreceptors followed by progressive loss through apoptotic cell death is characteristic of many hereditary retinal degeneration diseases in mice, but differs dramatically from the rapid degeneration before p20 seen in Pde6b\(^{104} \) mice (Carter-Dawson et al., 1978).

In the later stages of development (Fig. 6), some Tg737 mutant photoreceptors are grossly aberrant, whereas others exhibit relatively normal morphology, but even here, discs are generally significantly larger in diameter than those in wild-type photoreceptors. Although the mouse has a rod-dominant retina, the small population of cones is also disrupted (unpublished data), as would be expected if IFT88 were functioning in both photoreceptor types. In addition, retinas sampled at p21, and later, accumulate amorphous membrane vesicles in the extracellular space between cells (Fig. 6, B and D). These vesicles may be vesiculated pieces of photoreceptors that accumulate because of disrupted transport into the OS. The degenerative changes in Tg737 retinas appear to be related specifically to OSs and the death of photoreceptors. Therefore, the overall reduction in retinal thickness observed in Tg737 mutant mice can be accounted for as loss from the OS, IS, and photoreceptor nuclear layers (Fig. 5).

Figure 4. Rod cell OSs are abnormal and opsin is mislocalized in Tg737 mutant mice at p21. (a and b) Toluidine-blue–stained sections illustrating that mutant OSs (b) are less organized and less densely packed than those in similar sections of wild type (a). (c and d) Immunocytochemistry of rod opsin (red) and IFT88 (green) in frozen sections of wild-type (c) and Tg737 mutant (d) retina at p21. Both wild-type and mutant animals show strong opsin staining of the rod OS, but opsin is also detected in IS and around nuclei (ONL) in the mutant. IFT88 is present in the IS (c) but diminished in the mutant (d). (e and f) Electron micrographs of the junction between the IS and OS layers illustrating that mutant (f) photoreceptors are less uniform in structure and organization than wild-type photoreceptors (e) and accumulate extracellular vesicles (EV). Other abbreviations are the same as in figures 2 and 3. Bars: (a and b) 20 \( \mu \text{m} \); (c and d) 40 \( \mu \text{m} \); (e and f) 1 \( \mu \text{m} \).

Figure 5. Light microscopic images demonstrating progressive loss of photoreceptors in Tg737 mutant mice. (A) Full thickness section of typical wild-type retina at p77. (B–D) Full thickness views of retinas from Tg737 mutant mice at p45, p77, and p84, showing loss of nuclei from the ONL and progressive thinning of the IS and OS layers. All images are from 1-\( \mu \text{m} \)-thick plastic sections stained with toluidine blue. Other abbreviations: G, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; OPL, outer plexiform layer. Bar, 20 \( \mu \text{m} \).
Tg737 mice accumulate opsin in ISs and extracellular vesicles

Immunofluorescence microscopy (Fig. 4) indicated that the mutant photoreceptors retain opsin in their ISs and cell bodies. To more closely examine the targeting of proteins from the IS to the OS, we used postembedment immunocytochemistry. At p21 we studied the distribution of rod opsin, the most abundant OS protein, and ROM1, a protein localized in a complex with peripherin/rds at disc edges that is necessary for normal OS formation (Clarke et al., 2000). Both opsin and ROM1 are highly localized to the rod OSs in wild-type photoreceptors (Fig. 7). Opin is found throughout the disc membrane, whereas ROM1 is associated specifically with disc edges adjacent to the OS plasma membrane. In Tg737 mutant photoreceptors, both proteins are present in OSs. However, opsin is found in much higher concentrations compared with wild type in the IS plasma membrane and connecting cilium. In addition, opsin is present in the extracellular vesicles (EV) that are not found in wild-type animals. In Tg737 mutant photoreceptors, ROM1 is localized at disc edges and at incisures in wild-type animals. A similar pattern is detected in those Tg737 mutant rods that exhibit organized discs (f), but ROM1 appears to be much less abundant in OS with disorganized discs (g).
**Discussion**

**IFT particle proteins and photoreceptor development**

Our data provide evidence that IFT is important for normal development and maintenance of photoreceptor cells. We show that four proteins, identified by homology to components of the *Chlamydomonas* IFT particle (Cole et al., 1998), cosediment at ~17S in sucrose density gradients, consistent with their functioning as part of a mammalian IFT particle. These four proteins copurify with photoreceptor ciliary axonemes, and localize immunocytochemically to the basal body and connecting cillum of intact photoreceptors. Additional data indicate that IFT proteins are also associated with photoreceptor cilia of the fish and frog (unpublished data). The accumulation of these proteins at the basal body with lesser amounts in the ciliary axoneme is remarkably similar to the distribution of IFT particle proteins in *Chlamydomonas* (Cole et al., 1998; Pazour et al., 1999; Deane et al., 2001).

The critical importance of IFT in photoreceptors is demonstrated by our data showing that a hypomorphic mutation in the mouse Tg737/IFT88 gene leads to aberrant rod OS development and progressive photoreceptor degeneration, resulting in loss of 60–80% of the photoreceptors by p77. The basic features of the photoreceptor defect are initial aberrant, dysplastic development of both rod and cone OSs, followed by progressive photoreceptor death by apoptosis. During initial OS formation, discs fail to properly align and often are vesiculated or form parallel to the connecting cillum. Frequently, formation of the cillum occurs at sites distant from the apical region of the IS, leading to the formation of cells with anomalous polarity. Although disc rims form in many cells, discs are often unusually large, suggesting disruption of the mechanisms that normally regulate disc size. Interestingly, *rom1* mutant mice also form over-sized disks (Clarke et al., 2000), and in Tg737 mutant mice, ROM1 is reduced in severely disrupted OSs. In addition to the OS structural defects, Tg737 mutant mice retain opsin in their ISs and cell bodies, and accumulate extracellular vesicles containing opsin. However, opsin trafficking is not completely disrupted as large amounts of opsin are transported to the OSs. The photoreceptor cells still alive at p77 had aberrant OSs similar to those seen early in development.

In *Chlamydomonas* and *C. elegans*, Tg737/IFT88 is absolutely required for assembly of ciliary structures (Pazour et al., 2000; Qin et al., 2001). The assembly of the connecting cillum and its development, albeit abnormal, into a rod OS in the Tg737 mutant mouse is probably made possible by the presence of a small amount of Tg737/IFT88 made from the Tg737 insertional allele. The Tg737 insertional mutation, which was generated by integration of exogenous DNA into an intron without affecting the coding potential of adjacent exons, greatly reduces but does not eliminate the production of normal-sized Tg737 message (Moyer et al., 1994) and protein (Taulman et al., 2001; unpublished data).

During the course of this work, we examined the retinas from 29 mice of various ages that were homozygous for the Tg737 mutant allele and 55 that were heterozygous or homozygous for the wild-type Tg737 allele. In all cases, the homozygous Tg737 mutant animals had abnormal photoreceptors, whereas the heterozygotes and homozygous wild-type animals had normal retinas. No differences were observed between homozygous wild-type and heterozygous mutant eyes, indicating that the Tg737 mutation is fully recessive with regard to retinal degeneration, as it is for other phenotypes (Moyer et al., 1994).

Although the original Tg737 mutant mouse also contained the Pde6a1 mutation, which causes retinal degeneration, the mice used in this study were the products of outcrossings that eliminated one or both copies of the Pde6a1 mutation. The retinal defects described here were not caused by the Pde6a1 mutation, because they were observed in mice that were homozygous for the wild-type Pde6 allele. Furthermore, there was no interaction between the Tg737 and Pde6a1 mutant alleles, because Tg737+/− mice on a background that was either heterozygous Pde6+/− or homozygous wild type at the Pde6 locus had indistinguishable defects in OS formation.

Retinitis pigmentosa (RP) is a clinically and genetically heterogeneous group of retinal degeneration diseases in which photoreceptors are lost progressively through apoptotic cell death. Numerous gene mutations causing RP have been identified (http://www.sph.uth.tmc.edu/RetNet). Many of these are in retina-specific genes such as *Pde6* (Bowes et al., 1990; Pittler and Baehr, 1991), opsin (Li et al., 1996), peripherin/rds (Travis et al., 1991), or ROM1 (Clarke et al., 2000). Other RP-causing mutations are in genes with broader expression patterns, such as myosin VIIA, which causes RP and deafness (Liu et al., 1999). Because IFT is important for the assembly and maintenance of all cilia and flagella, defects in IFT would also be expected to affect multiple cell types and tissues. Indeed, the Tg737 mutant mouse is defective in assembly of the primary cillum in the kidney, leading to polycystic kidney disease (Pazour et al., 2000). Thus, it is of interest that there is a longstanding connection in the literature between RP and polycystic kidney disease (see “266900 renal dysplasia and retinal aplasia” at the online Mendelian inheritance in man website, www3.ncbi.nlm.nih.gov/htbin-post/Omim/dispomim/266900). For example, both Senior-Loken and Jeune syndrome, which appear to be separate diseases, are characterized by retinal degeneration and cystic kidneys (Traboulsi et al., 1998). Tg737/IFT88 and other IFT components are likely candidates for causing these hereditary systemic disorders involving RP.

Mouse models have proved instrumental in providing insight into the mechanisms leading to degeneration, and the Tg737 mutation adds to a growing list of gene defects that appear to cause photoreceptor degeneration through disruption of pathways essential for normal assembly of the OS. Phenotypic similarities among Tg737 (this paper), pcd (Blanks and Spec, 1992), rdS (Travis et al., 1991), Tulp1+/− (Hagstrom et al., 1999), myosin VIIA+/− (Liu et al., 1999), KIF3A+/− (Marszalek et al., 2000), and Rom1+/− (Clarke et al., 2000) mutants include formation of abnormally large discs, accumulation of extracellular vesicles, and accumulation of opsin within IS or ciliary membranes. Recently, it has been found that both overly large discs in Rom1+/− mice (Clarke et al., 2000) and the accumulation of extracellular vesicles in Tulp1+/− mice (Hagstrom et al., 1999) were associated with defects in photoreceptor trafficking.
are associated with failed OS assembly. Strikingly, we find both structural alterations in Tg737 mutant mice, arguing further that IFT provides a transport mechanism critical for normal assembly.

Model for intraphotoreceptor transport
Our data allow us to propose a model (Fig. 8) based on the idea that one or more of the cytoskeletal, membrane (including rhodopsin, peripherin-2, Rom-1, and phospholipid), or cytosolic protein components (including IFT proteins) normally synthesized in the IS and targeted to the OS via the connecting cilium are transported via IFT. The macromolecules are all synthesized in the IS. The polarity of IS microtubules (Trout and Burnside, 1988), with their minus ends associated with the base of the cilium, suggests that membrane vesicles are transported there by cytoplasmic dynein 1. This dynein is a well-established vesicle transporter and has been shown to interact with the cytoplasmic tail of rhodopsin (Tai et al., 1999). At the base of the connecting cilium where IFT particle proteins are most concentrated, the IFT particles associate with the surface of the vesicles and components of the ciliary axoneme, as well as soluble proteins of the OS such as transducin and arrestin. Once the vesicles fuse with the plasma membrane adjacent to the cilium, the complex is moved along the connecting cilium by kinesin-II. Kinesin-II is the anterograde IFT motor in Chlamydomonas (Kozminski et al., 1993; Cole et al., 1998) and Caenorhabditis (Orozco et al., 1999; Signor et al., 1999b). Kinesin-II has been localized to the connecting cilium in vertebrates (Beech et al., 1996; Whitehead et al., 1999), and mice with photoreceptor-specific defects in the KIF3A subunit of kinesin-II accumulate opsin and arrestin in the IS (Marszalek et al., 2000). In the OS, the IFT particles disengage from their cargo, and the membrane is organized into disks through a mechanism involving myosin VIIA. Myosin VII is required for phagocytosis in Dictyostelium (Titus, 1999), and mice with defects in the myosin VIIA gene accumulate opsin in the connecting cilium (Liu et al., 1999). Soluble proteins of the transduction machinery and cytoskeleton then associate with appropriate protein complexes within the IS, and IFT particles that have reached the distal end of the connecting cilium are returned to the base of the cilium by cytoplasmic dynein 1b/2. This dynein is the retrograde IFT motor in Chlamydomonas (Pazour et al., 1998, 1999; Porter et al., 1999) and Caenorhabditis (Signor et al., 1999a) and has been localized to the connecting cilium of vertebrate photoreceptors (unpublished data). At the base of the connecting cilium, the IFT particles reenter a peribasal body pool of IFT particle proteins and begin the cycle again. The IFT particles also may move components of the transduction machinery from the OS to the IS. For example, both transducin and arrestin have been reported to rapidly move between the segments during light and dark adaptation (Philp et al., 1987; Whelan and McGinnis, 1988), and arrestin accumulates in the IS in KIF3A mutant mice (Marszalek et al., 2000).

Comparison to kinesin-II Cre-Lox mice
The recent finding (Marszalek et al., 2000) that a conditional knockout of the KIF3A subunit of kinesin-II in mouse photoreceptors results in photoreceptor degeneration

Comparison to kinesin-II Cre-Lox mice
The recent finding (Marszalek et al., 2000) that a conditional knockout of the KIF3A subunit of kinesin-II in mouse photoreceptors results in photoreceptor degeneration

is similar to our findings for the Tg737 mutation. Both mutations cause accumulation of opsin in the IS and result in substantial age-related loss of photoreceptors. The principal difference in the two phenotypes is that kinesin-II mutant mice accumulate intracellular vesicles in the IS before degeneration of affected cells, whereas Tg737 mutant mice accumulate extracellular vesicles and show anomalous OS development before degeneration. Although the initial IS defect in the KIF3A mutant mice may reflect a nonciliary role for kinesin-II in photoreceptors, it seems likely that the principal differences between the two relates to the fact that the kinesin-II defect appears suddenly in individual cells after the OSs have developed (Marszalek et al., 2000), whereas the hypomorphic Tg737 mice have an insufficient quantity of IFT88 during development and do not form proper OSs. In both the Tg737 and the kinesin-II mutant mice, opsin accumulates within the IS, and it has been suggested that kinesin-II specifically transports opsin (Marszalek et al., 2000).
Although opsin is a potential cargo for IFT, its accumulation in IS membranes is a general feature of diverse photoreceptor degenerations (Nir and Papermaster, 1986; Nir et al., 1987; Hagstrom et al., 1999) and could result indirectly from multiple defects that alter the transport/assembly of discs in the OS. Current work directed at identifying proteins that interact with IFT particles may provide insight into the specific cargo delivered through IFT.

Materials and methods

Cloning IFT20

*Chlamydomonas* IFT20 was purified, and the sequences of two tryptic peptides (GVYFDEDFHVR and YVSAIDQQVER) were obtained (Cole et al., 1998). A degenerate PCR primer designed from the first peptide sequence was used in combination with an oligo-dT primer to amplify most of the coding sequence from reverse-transcribed cDNA. The remainder of the gene was amplified from a *Chlamydomonas* cDNA library in lambda ZapII (Stratagene) with a vector primer (M13Rev) and a IFT20-specific primer designed from the sequence of the first PCR product. The open reading frame contained within these clones encodes a 15.6-kD peptide containing both tryptic peptides.

Antibody production

The antibodies were produced in rabbits by injecting bacterially expressed maltose-binding fusion proteins made by cloning the entire open reading frames of mouse NDG5 (IFT52), IFT75, and IFT20, and the COOH-terminal 459 codons of Tg373 (IFT88) into the pMALc expression vector (New England Biolabs, Inc.). The sera were affinity purified using immobilized glutathione-S-transferase fusion proteins. The latter fusion proteins were made by cloning the open reading frames of the IFT genes into the pGEX-6p-1 (Amersham Pharmacia Biotech) expression vector.

Preparation of the DEPC and Western blotting

Whole retinal extracts of mouse and bovine retina were prepared by direct solubilization in SDS sample buffer. The DEPC was prepared as described by Horst et al. (1987). In brief, rod OSs shaken from 50 dark-adapted, frozen bovine retinas in buffer A (10 mM Pipes, pH 7.0, 1 mM EDTA, 5 mM MgCl$_2$, 0.02% NaN$_3$, supplemented with a protease inhibitor cocktail (1 µg/ml pepstatin, 1 µg/ml leupeptin, 4 µg/ml aprotinin, 1 mM benzamidine, 1 mM PMSF), were purified by sucrose density centrifugation. OSs were then extracted in buffer A containing 2% Triton X-100. Ciliary axonemes were separated from detergent-soluble material by centrifugation over a 45–60% linear sucrose gradient. Equal aliquots were separated on a 12% denaturing polyacrylamide gel and transferred to Immobilon-$
\Sigma$ membranes for antibody labeling and detection using the SuperSignal West Femto chemiluminescent system (Pierce Chemical Co.). The Western blot analysis of mutant mouse retinal tissue with IFT88 antibodies was conducted on homozygous mutant and wild-type mice at p21.

Sucrose gradient analysis

Sucrose density gradient analysis was performed according to the procedures of Cole et al. (1998) using five frozen mouse testes (0.5 g of tissue; Pel-Freez Biologicals). Tissue was thawed, diced, and homogenized for 2 min in a Dounce homogenizer in 0.5 ml of HMDEK buffer (Cole et al., 1998) containing protease inhibitors: 2.5 mM 4-aminobenzamidine, 2.0 mM PMSF, 1 µg/ml pepstatin A, 1 µg/ml aprotinin, 1 µg/ml leupeptin, and 50 µg/ml soybean trypsin inhibitor. After 10 min on ice, the homogenate was centrifuged (16,000 g for 10 min at 4°C), and the supernatant was further centrifuged (178,000 g; Beckman Airfuge) for 5 min at 25°C. NaCl was added to a final concentration of 300 mM and the supernatant was fractionated on a 5–20% linear sucrose gradient containing 300 mM NaCl in HMDEK.

Immunofluorescence and confocal imaging

Fresh mouse or bovine retinal tissue was placed in Tissue Freezing Medium (Electron Microscope Sciences) and quickly frozen in liquid nitrogen with or without prior fixation in 4% paraformaldehyde. For the immunofluorescence of mouse retina in Fig. 1, tissue was fixed in paraffin. After removal of the paraffin, the sections were boiled for 10 min in 10 mM sodium citrate (pH 6) and treated with 0.1% sodium borohydride in PBS for 30 min. For the immunofluorescence of mouse retina in Fig. 4, frozen sections were boiled for 15 min in 10 mM sodium citrate buffer. Primary antibodies were detected with goat anti-rabbit or goat anti-mouse IgG conjugated with Cy3 (Jackson Immunoresearch Laboratories, Texas red, fluorescein, Alexa 488, Alexa 568, or Alexa 633 (Molecular Probes). In double label experiments, discrimination of signals for K26 versus IFT proteins involved the use of conjugated anti–mouse and anti–rabbit antibodies, respectively. For discrimination of two monoclonal antibodies (K26 vs. tubulin or opsin), we labeled with one monoclonal antibody and a fluorescent anti–mouse antibody, and then repeated the procedure for the second monoclonal antibody using a different fluorophore. Images of cells labeled with more than one fluorophore were pseudocolored and merged using NIH Image 1.62 or Adobe Photoshop. Antibodies used in these studies were the four IFT antibodies (above), an antirhodopsin monoclonal antibody (B630N; Besharse and Wetzel, 1995), a monoclonal anti-acetylated α-tubulin antibody (611B1; Sigma-Aldrich), an antibody to ROM1 (provided by Rod McInnes, University of Toronto, Toronto, Canada), and a monoclonal antibody (K26) directed at an unidentified epitope of the bovine photoreceptor connecting ciliun (Horst et al., 1990).

Mouse breeding

The original TgN737Rpw mouse line was homozygous for the autosomal recessive *Pdebrd1* retinal degeneration defect, precluding analysis of the effect of the Tg373 mutation on retinal development. To produce animals suitable for analysis, heterozygous Tg373 mutant mice on the FVB/N (+/TgN737Rpw, *Pdebrd1*+/Pdebrd1) background were bred to wild-type C57Bl6/j (+/+, +/+ ) animals, and the offspring from this cross were sibling mated to produce F2 animals, or backcrossed to the heterozygous Tg373 FVB/N parent. The Tg373 mutation was genotyped as described by Pazour et al. (2000). Pdebrd1 was genotyped using a Dde1 restriction site polymorphism (Pitler and Baehr, 1991) that results from the Pdebrd1 mutation.

EM

For conventional EM, eyes of Tg373 mutant animals and littermate controls were removed at p10, p21, p45, and p77. At least six Tg373/+ mutant eyes and Tg373—/— controls were analyzed at each age; one additional mutant was examined at p84. After making an incision in the cornea on the dorsal side, eyes were fixed by immersion in 2.5% glutaraldehyde and 2% formaldehyde in phosphate buffer for 1–2 d. The cornea, iris, and lens were then surgically removed and the eye cups were postfixed in 1% osmium tetroxide for 2 h, dehydrated in ethanol, and embedded in Embed 812 (Electron Microscopy Sciences). At the time of embedding, eyes were oriented so that sections could be obtained parallel to the dorsoventral meridian. 1-µm-thick sections were stained with toluidine blue, and silver–gold thin sections were stained with uranyl acetate and lead citrate after conventional procedures. All analyses were conducted on cells in the central retina (posterior pole) in sections through the dorsoventral meridian.

Postembedding EM immunocytochemistry

For postembedding EM immunocytochemistry, eyes from Tg373 mutant animals and littermate controls at p21 were removed and fixed in 4% paraformaldehyde in phosphate buffer for 1–2 d. They were then dehydrated in ethanol and embedded in Embed 812 (Electron Microscopy Sciences). At the time of embedding, eyes were oriented so that sections could be obtained parallel to the dorsoventral meridian. 1-µm-thick sections were stained with toluidine blue, and silver–gold thin sections were stained with uranyl acetate and lead citrate after conventional procedures. All analyses were conducted on cells in the central retina (posterior pole) in sections through the dorsoventral meridian.

Image processing was limited to adjustments of brightness and contrast.

GenBank/EMBL/DDJB accession nos.

IFT20: *Chlamydomonas* accession no. AF285762, Xenopus (AY048114), chicken (BG711517), pig (BF075374), cattle (AV597208), rat (AI170881), mouse (AA099304). IFT52: mouse (AAA96241, AY082613), and human (AA099304). IFT88: mouse (NP033042, AY082613), chicken (BG711517), pig (BF075374), cattle (AV597208), rat (AI170881), mouse (AA099304), and human (AA099304). IFT57: mouse (AA099304).

The authors thank Wolfgang Baehr (Moran Eye Center, Salt Lake City, UT) and Dennis Diener (Yale University, New Haven, CT) for helpful discussions, Rod McInnes for the ROM-1 antibody, and Scott Seeley and Marleen Janson for technical support. We also thank Greg Hendricks from the University of Massachusetts Medical School (UMMS) EM facility, Greg Ning from the Medical College of Wisconsin (MCW) EM facility, and Anna
