Multiprotein complexes are key determinants of Golgi apparatus structure and its capacity for intracellular transport and glycoprotein modification. Three complexes that have previously been partially characterized include (a) the Golgi transport complex (GTC), identified in an in vitro membrane transport assay, (b) the ldlCp complex, identified in analyses of CHO cell mutants with defects in Golgi-associated glycosylation reactions, and (c) the mammalian Sec34 complex, identified by homology to yeast Sec34p, implicated in vesicular transport. We show that these three complexes are identical and rename them the conserved oligomeric Golgi (COG) complex. The COG complex comprises four previously characterized proteins (Cog1/ldlBp, Cog2/ldlCp, Cog3/Sec34, and Cog5/GTC-90), three homologues of yeast Sec34/35 complex subunits (Cog4, -6, and -8), and a previously unidentified Golgi-associated protein (Cog7). EM of ldlB and ldlC mutants established that COG is required for normal Golgi morphology. “Deep etch” EM of purified COG revealed an ~37-nm-long structure comprised of two similarly sized globular domains connected by smaller extensions. Consideration of biochemical and genetic data for mammalian COG and its yeast homologue suggests a model for the subunit distribution within this complex, which plays critical roles in Golgi structure and function.

Introduction

The eukaryotic secretory pathway consists of a set of membrane-bound compartments through which proteins move in transport vesicles or larger transport intermediates (Rothman, 1994). Vesicular transport from one compartment to the next can be divided into four sequential phases: vesicle budding; movement to the next compartment; association of the vesicle with the acceptor compartment; and fusion of vesicle and acceptor membranes (Rothman, 1994; Mellman and Warren, 2000). For the Golgi apparatus, the transport structures may be the Golgi cisternae themselves, as some secretory cargo moves through the Golgi without exiting the stack in vesicles (Bonfanti et al., 1998; Mironov et al., 2001).

Many Golgi proteins, such as glycosylation enzymes, are maintained in a nonuniform steady-state distribution through the cisternae. These proteins must be transported to their sites of residence and then either be retained there or, if they move beyond them, retrieved by retrograde vesicular transport (Harris and Waters, 1996; Martinez-Menarguez et al., 2001). Thus, all transport steps appear to involve the movement of small vesicles (either carrying cargo in the anterograde or resident enzymes in the retrograde direction) between larger membrane compartments (Pelham and Rothman, 2000).

Studies in yeast and mammalian cells have led to the identification of several multisubunit peripheral membrane protein complexes that are thought to be involved in membrane trafficking and/or compartment function, including the Sec6/8 (Grindstaff et al., 1998; Guo et al., 1999), the TRAPP I (Sacher et al., 2001), and the Sec34/35 (VanRheenen et al., 1998) complexes. The yeast Sec34/35 complex has
eight subunits (Whyte and Munro, 2001), is localized to the Golgi apparatus (Spelbrink and Nothwehr, 1999; Kim et al., 2001), and has been suggested to be involved in anterograde ER to Golgi (VanRheenen et al., 1998; Kim et al., 2001), retrograde intra-Golgi (Ram et al., 2002), and endosome to Golgi (Spelbrink and Nothwehr, 1999) traffic. A mammalian Sec34-containing complex has also been identified and implicated in Golgi protein trafficking (Suvorova et al., 2001).

Another complex, called the Golgi transport complex (GTC), was isolated because of its ability to stimulate an in vitro intra-Golgi transport assay (Walter et al., 1998). It is a hetero-oligomeric Golgi-localized complex of ~800 kD, comprising proteins between 70 and 110 kD. The 90-kD subunit of GTC, GTC-90, was identified and a cDNA encoding the protein was cloned.

The ldlCp complex was discovered during the analysis of low-density lipoprotein receptor (LDLR)–defective CHO cell mutants, ldlB and ldlC (Krieger et al., 1981; Podos et al., 1994; Chatterton et al., 1999). The ldlB- and ldlC-null mutants, which are viable, exhibit defects in multiple Golgi-associated reactions that result in the abnormal processing of the LDLR and many other glycoconjugates (Kingsley et al., 1986). The defects are not due to drastic disruptions in secretion or endocytosis (Kingsley et al., 1986; Reddy and Krieger, 1989). The ldlCp protein (~80 kD) is a component of a large peripheral Golgi complex whose size and Golgi-association are dependent on ldlBp (~110 kD) (Podos et al., 1994; Chatterton et al., 1999), which suggested that they are components of the same complex.

Similarities in the sizes, locations, and subunits of the ldlCp complex and GTC suggested that they might be identical (Chatterton et al., 1999). We have explored this possibility through identification of all the subunits of purified GTC and examination of the physical association of the proteins in tissues and wild-type and mutant cultured cells. We have found that GTC and the ldlCp complexes are the same, and it appears to be to the mammalian homologue of the yeast Sec34/35 complex. This is consistent with the report of Whyte and Munro (2001; which appeared during the preparation of this manuscript), which showed that the yeast homologue of GTC-90, Cod4p, is a subunit of the Sec34/35 complex. We suggest that this mammalian complex be called conserved oligomeric Golgi (COG) complex, and its subunits be designated Cog1–8. We have also examined by EM the structure of the COG complex and the effects of the null mutations in ldlB (Cog1) and ldlC (Cog2) on Golgi structure.

Results

Improved COG complex purification

We modified the previously described (Walter et al., 1998) method of COG purification from bovine brain to improve the yield (Table I) and followed the purification by anti-Cog5 immunoblotting. During the purification, two peaks of Cog5 were resolved by hydroxyapatite chromatography (Fig. 1 A). Similar complexes were also seen in CHO cell lysates not subjected to the multiple purification steps (see Fig. 7 B). We purified the protein eluting in the second peak because it represented the larger complex (Fig. 1 B), here defined as COG. It is not clear if both complexes are present in vivo or if the small complex was generated during cell/tissue lysis, or if the peak 1 material, which is slightly smaller in size than COG (Fig. 1 B), shares COG components other than Cog5.

SDS-PAGE analysis of the fractions from the final purification step (Table I and Fig. 2) indicated that COG is composed of eight subunits. If one copy of each subunit were present in the complex, the calculated molecular weight would be 700 kD.

Identification of subunits of the mammalian COG complex

Purified COG subunits were excised from the SDS-PAGE gel individually (Cog1, -2, -6, and -8) or in pairs (Cog3/
COG, a conserved oligomeric Golgi protein complex

The COG complex is a conserved protein complex found in various eukaryotic cells. It is composed of eight protein components, identified by mass spectrometry and immunoblotting. The proteins Cog1, Cog2, and Cog3 were identified as ldlBp, ldlCp, and the homologues of yeast Cod2p and Dor1p, respectively. The proteins Cog4 and Cog7 were identified as the mammalian Sec34 and GTC-90, and Cog5 and Cog4/Cog7, respectively. The proteins Cog3/Cog5 were identified as the mammalian Sec34 and GTC-90, and Cog4/Cog7 as the homologue of yeast Cod1p.

Cog7 is conserved in higher eukaryotes

The human Cog7 cDNA encodes a protein of 770 residues, which is conserved in various mammalian Golgi-associated complexes. The presence of Cog7 in the purified material was confirmed by immunoblotting partially (Fig. 3) and completely (Fig. 2 A) purified fractions. Although present in the COG complex, the Cog1, -2, and -3 subunits were not detected by immunoblotting in the smaller Cog5-containing complex (Fig. 3, fractions 30–32).

The COG complex was purified from bovine brain cytosol using a combination of ammonium sulfate precipitation, butyl-Sepharose chromatography, and MonoQ chromatography. The purified complex was subjected to ceramic hydroxyapatite chromatography, and the subunit composition of the small and large Cog5-containing complexes was compared.

**Figure 2.** MiniQ purification of COG and identification of its subunits. (A) Peak 2 from the ceramic hydroxyapatite chromatogram in Fig. 1 A was further purified (Table I), and a portion of each fraction from the last chromatographic step (MiniQ) was subjected to 7.5% SDS-PAGE and silver staining (top; molecular weight markers [kD] shown on the left) or 10% SDS-PAGE and immunoblotting (bottom four panels) with antibodies to the indicated proteins. To resolve the individual bands, the 7.5% SDS-PAGE gel was run until proteins smaller than 60 kD ran off the gel. No additional components (or contaminants) were detected in the size range below 65 kD (verified by 15% SDS-PAGE; unpublished data). The load lane is the sample before chromatography. (B) Enlarged view of the lower portion of the lane containing fraction 19 in A. The indicated identities of the proteins were determined by mass spectrometry, as described in the text. The pairs marked by brackets were excised together and sequenced as a mixture. The protein marked with an asterisk is rabaptin-5, which is not part of the complex (A). The positions of molecular weight (kD) markers are shown on the left.

**Figure 3.** Comparison of the subunit composition of the small and large Cog5-containing complexes. Partially purified COG complex (purified by ammonium sulfate precipitation, butyl-Sepharose chromatography and MonoQ chromatography) was subjected to ceramic hydroxyapatite chromatography. Samples of the fractions were separated by 10% SDS-PAGE and subjected to immunoblotting with antibodies specific to the indicated proteins as described in the legend to Fig. 1 A. Labels are as in Fig. 1 A.

Percent identity and percent similarity were calculated using the GCG software package (Wisconsin package version 10.2). The GenBank/EMBL/DDBJ accession nos. for the human Drosophila melanogaster and Arabidopsis thaliana proteins are XP_041725, AAF56975, and BAB09754, respectively.
fixed samples suggest that COG is bilobed. In some images, the lobes appeared to be interconnected by thin rods and/or globules. The fixed form was 37 ± 4 \(\mu\)m long. Thus, COG appears to be slightly larger than the size marker thyroglobulin (670 kD; Fig. 6, leftmost in bottom row). The bilobed appearance of COG looks substantially different than comparable images of the mammalian Sec6/8 complex (Fig. 6, first four images in fifth row). The Sec6/8 complex appears to have a large globular or brick-shaped “core” that is surrounded by short extensions (Hsu et al., 1998). Other molecules suitable for comparison in size and shape with COG are shown in the bottom panels of Fig. 6 and are described in its legend. About a third of the images of unfixed COG (Fig. 6, unfixed) appeared similar to the fixed samples, whereas the others appeared somewhat heterogeneous and “splayed.” The splayed images tended to display two globules connected by disordered globular or rod-like connections. The splayed forms ranged up to 50–75 nm long. The overall size of this form was similar to that of a clathrin triskelion (Fig. 6, fourth image in row 5; Heuser and Kirchhausen, 1985). Presumably, such splayed forms represent COG complexes partially disassembled by adhesion with mica. Nevertheless, they illustrate that native COG seems to be a group of globular domains interconnected by flexible arms. Additional studies will be required to determine if the native COG within cells is a tightly compacted, bilobed, or a relatively splayed structure.

Effects of COG mutations on its composition and size and on the structure of the Golgi apparatus

The Cog1 and Cog2 proteins were initially identified during the analysis of two classes of CHO cell mutants, IdlB and IdlC (Krieger et al., 1981; Kingsley et al., 1986; Podos et al., 1994; Chatterton et al., 1999). We used immunoblotting of whole cell lysates to determine the steady-state levels of COG subunits in wild-type and mu-
tant cells, as well as stable transfectants in which the mutants’ phenotypes were corrected by transfection with expression vectors encoding either Cog1 (ldlB\[COG1\]) or Cog2 (ldlC\[COG2\]). Fig. 7 A shows that, as previously described (Podos et al., 1994), Cog2 was not detected in the ldlC mutant (lane 4), whereas a somewhat greater than wild-type expression level of Cog2 was observed in ldlC\[COG2\] cells. Similar results were obtained for Cog1 expression in wild-type (lane 1), ldlB (lane 2), and ldlB\[COG1\] cells (lane 3), as expected from prior studies (Chatterton et al., 1999). In ldlB cells, the level of Cog5 was significantly lower (lane 2) than in the wild-type (lane 1) or transfectant (lane 3) controls, but the levels of Cog3 and Cog2 were not altered. In contrast, the levels in ldlC cells of Cog1, -3, and -5 were dramatically reduced (lane 4) compared with wild-type (lane 1) or transfected (lane 3) controls. The residual level of Cog5 in ldlC cells (lane 4) was similar to that in ldlB cells (lane 2). The absence of Cog1 (lane 2) or Cog2 (lane 4) did not alter the levels of components of two other complexes involved in secretion, β-COP and Sec8 (Fig. 7 A). Thus, the absence of some COG subunits affected the steady-state levels of other COG components, providing genetic evidence for their interactions. The different effects of the absence of Cog1 and Cog2 on the levels of other COG subunits suggest that Cog1 and Cog2 play distinct roles in the organization of the complex.

The absence of one or more subunits in a macromolecular assembly, such as COG, should alter the size of the residual complex. We size fractionated wild-type (Fig. 7 B, top), ldlB (middle), and ldlC (bottom) cytosols and examined the distribution of the Cog1, -2, -3, and -5 subunits by immunoblotting. In wild-type cytosol, Cog1, -2, -3, and -5 comigrated (Fig. 7 B, fractions 21 and 22), and we detected a distinct, smaller complex containing Cog5 but not the other immunodetectable COG components (fractions 23–26, compare with Fig. 3, peak 1). In ldlB (Cog1) cytosol, the other COG subunits were no longer present in the large complex (Fig. 7 B, fractions 21 and 22; Chatterton et al., 1999). Rather, their mobilities showed, in addition to the Cog5 present in the smaller complex (fractions 23–26), that they were components of an even smaller entity whose size was much larger than that expected for the individual subunits. In the ldlC (Cog2) mutant, where the steady-state levels of total cellular Cog3 and Cog5 were significantly reduced (Fig. 7 A), these subunits were no longer found in the large complex (Fig. 7 B, fractions 21 and 22). These data support the conclusion that Cog1, -2, -3, and -5 are components of one large complex. They also show that in CHO cells, as was the case for bovine brain cytosol, some Cog5 was present in a distinct complex that was smaller than COG and did not contain Cog1, -2, and -3. The chromatographic mobility of this smaller Cog5-containing complex was apparently unperturbed by the absence of Cog1 or Cog2.

The disruptions in the size and composition of COG in ldlB and ldlC mutants (Fig. 7) are associated with pleiotropic Golgi functional defects (Kingsley et al., 1986; Podos et al., 1994; Chatterton et al., 1999). Therefore, we examined,
by transmission EM, the morphology of the Golgi apparatus in wild-type CHO, IdlB, and IdlC cells and their corresponding phenotypically corrected transfectants (IdlB-[COG1] and IdlC-[COG2]). Fig. 8 shows that the Golgi morphology in both IdlB and IdlC mutants was abnormal. At least half, and sometimes all, of the identifiable cisternae were dilated in the mutants. These dilated cisternae were not seen in control wild-type cells or transfectants, suggesting that they were related to the functional defects in IdlB and IdlC mutants. Additional studies will be required to determine if the dilated cisternae are located predominantly on the cis or trans sides of the Golgi stack.

Discussion

The components of the COG complex

We characterized the composition, structure, and function of a mammalian conserved oligomeric Golgi-localized protein complex, the COG complex. Purification of COG and identification of its subunits, Cog1–8, showed that some of its polypeptides are known components of the GTC, the ldlCp complex, and the Sec34 complex (Table II). Coimmuno-precipitation experiments showed that COG components (Cog1, -2, -3, and -5) are physically associated. Furthermore, the steady-state levels of some COG subunits (Cog1, -2, -3, and -5) were dramatically reduced in IdlB (Cog1) or IdlC (Cog2) mutants, establishing genetic associations between them. The loss of Cog1 or Cog2 in the mutants also led to a reduction in the sizes of the residual complexes. In addition, seven COG subunits (Cog1–5, -7, and -8) have been localized to the mammalian Golgi apparatus (Podos et al., 1994; Walter et al., 1998; Suvorova et al., 2001; Whyte and Munro, 2001; this study). Finally, independent analyses of the yeast Sec34/35 complex (Kim et al., 1999, 2001; VanRheenen et al., 1999; Whyte and Munro, 2001; Ram et al., 2002) show that it too is a hetero-octameric complex, and five of its subunits are close homologues of COG subunits (Cog3–6 and -8) (Table II). The remaining three subunits in the COG and Sec34/35 complex are also likely to be related functionally. Indeed, yeast Sec35p and Cog2 have limited sequence similarity (Whyte and Munro, 2001).

The structure of COG

Quick freeze/deep etch/rotary shadow EM suggests that COG, at least after fixation with glutaraldehyde, is ~37 nm long and divided into two almost equally sized lobes (designated A and B, see below). In unfixed specimens, we observed similar bilobed structures and, more frequently, splayed structures with multiple small globular domains connected by relatively flexible extensions (Fig. 6).

Insight into the relationship between the bilobed structure of COG and its subunit composition can be deduced from our studies in combination with studies of the yeast Sec34/35 complex (Fig. 9). During the COG purification, we noted that Cog5 was present both in COG (Fig. 1, peak 2) and in a smaller complex (Fig. 1, peak 1). The smaller complex may represent a fragment of the COG complex (Fig. 9, lobe B; see below), contain COG subunits in addition to Cog5 (see below), and thus correspond to one of the two lobes seen in the EM images. Because Cog1, -2, and -3 are
not part of the Cog5-containing smaller complex, they presumably reside in the other lobe. Division of COG into two approximately equal-sized lobes, each having four subunits, is consistent with the classification by Whyte and Munro (2001) of the yeast Sec34/35 complex’s subunits into two groups of four, based on the severity of their mutant phenotypes. The first group, characterized by more severe phenotypes, contains Sec34p, Sec35p, Cod1p, and Cod3p, whereas the other group, distinguished by weaker phenotypes, comprises Dor1p, Cod2p, Cod4p, and Cod5p (Whyte and Munro, 2001). We suggest that the stronger and weaker phenotypes are the result of mutations in subunits residing in distinct lobes of the complex; mutations in lobe A produce stronger phenotypes (e.g., sec34), and those in lobe B (e.g., cod4) give weaker ones (Fig. 9).

With this assumption we can assign other subunits to the A and B lobes of COG. The weak phenotype of the cod4 mutant places Cog5/Cod4p in lobe B and consequently Cog1, -2, and -3, which are in the other lobe, in lobe A (Fig. 9). Moreover, we propose that the fourth protein in lobe A is Cog4/Cod1p because of the severe cod1 phenotype (Kim et al., 2001; Whyte and Munro, 2001; Ram et al., 2002). Finally, the remaining proteins, Cog6–8, must reside in lobe B (Fig. 9), consistent with the weaker phenotypes of cod2 and dor1 mutants (Whyte and Munro, 2001), the yeast counter-parts of Cog6 and Cog8. The proposed composition of lobe B is consistent with it potentially representing the smaller Cog5-containing complex in bovine brain and CHO cell cytosols.

As a consequence of these assignments (Fig. 9 and Table IV), we suggest that Cog7 in lobe B is functionally analogous to yeast Cod5p. Lastly, we speculate that (a) Cog2 and yeast Sec35p are functional analogs because of their weak sequence similarities and assignments to the A lobes, and (b) the remaining unpaired subunits, Cog1 and yeast Cod3p in lobe A, are probably functional analogs (Fig. 9 and Table IV). Supporting this, mammalian Cog2 and Cog3, or the corresponding yeast Sec35p and Sec34p, comigrate at a smaller size when Cog1/Cod3p mutant cytosol is gel filtered (Fig. 7; Ram et al., 2002). Further work will be required to rigorously test this model for COG.

**The function of COG**

Cog1 and Cog2 were originally identified in a genetic screen for mutants that block LDLR activity in CHO cells (Krieger et al., 1981). Analysis of the transport/secretion of the LDLR and vesicular stomatitis virus (VSV) in ldlB and ldlC mutants and in a revertant of ldlC cells bearing an extragenic suppressor of the LDLLR-deficient phenotype (Reddy and Krieger, 1989) strongly suggested that neither membrane protein transport through the secretory pathway nor normal endocytic cycling are disrupted profoundly. The pleiotropic defects in Golgi–associated glycosylation reactions in these mutants resulted in abnormally glycosylated, and consequently unstable, LDLRs. The ldlB and ldlC cells have essentially identical defects in numerous medial- and trans-Golgi–associated reactions that affect virtually all protein- (N-linked and O-linked) and lipid-linked glycoconjugates (Kingsley et al., 1986). The pleiotropic nature of the defects suggested that the mutations might affect the regulation, compartmentalization, transport, or activity of several different Golgi enzymes and/or enzyme substrates, or the internal milieu of the Golgi apparatus. This correlates well with our finding in this study that Golgi cisternae are dilated in these mutants.

Another COG component, Cog3, was first identified (Walter et al., 1998) in an in vitro assay that measures glycosylation of a cargo protein as a consequence of a membrane fusion event (Balch et al., 1984). The assay is dependent on maintenance of an intraluminal environment that is compatible with glycosylation (Hiebsch and Wattenberg, 1992) and on vesicular transport factors, especially those involved...
in membrane docking or fusion (Block et al., 1988; Clary and Rothman, 1990; Waters et al., 1992; Legesse-Miller et al., 1998). Although this system was originally thought to measure anterograde vesicle traffic through the Golgi apparatus (Balch et al., 1984), it has been suggested (Love et al., 1998) that it may in fact measure retrograde traffic of the glycosyltransferase to the cargo and, as such, recapitulate retrograde intra-Golgi traffic. The fact that COG is active in this in vitro system suggests that it may act in docking and/or fusion of vesicles within the Golgi apparatus, possibly including retrograde glycosyltransferase-bearing vesicles.

Further insight into COG function can be derived from studies of its yeast homologue, the Sec34/35 complex. sec34 and sec35 exhibit slow growth, missorting of proteins in the secretory/vacuolar system, defective protein secretion, underglycosylation of proteins, accumulation of vesicles, and dilated membranous compartments (Wuestehube et al., 1996; Kim et al., 2001). Mutations in Sec34/35 complex subunits genetically interact with mutations in components involved in multiple steps of transport to and through the Golgi apparatus (VanRheenen et al., 1998; Kim et al., 1999, 2001; Spelbrink and Nothwehr, 1999; VanRheenen et al., 1999; Whyte and Munro, 2001; Ram et al., 2002). Of particular note is the recent observation that Sec34/35 complex components, which are located throughout the Golgi apparatus (Kim et al., 2001), show strong genetic interactions with subunits of the COPI vesicle coat (Kim et al., 2001; Ram et al., 2002), which is thought to function in retrograde traffic within the Golgi apparatus and from the Golgi apparatus to the ER (Letourneur et al., 1994). This prompted Ram et al. (2002) to suggest that the Sec34/35 complex may function in retrograde intra-Golgi traffic, a possibility we have independently considered for mammalian COG. Indeed, it is known that maintenance of Golgi enzymes requires their retrograde vesicular transport from distal compartments (Harris and Waters, 1996; Martinez-Menarguez et al., 2001). Thus, a defect in intra-Golgi retrograde traffic could lead to the glycosylation defects seen in mammalian and yeast COG mutants. Compromised COG activity might also contribute to an aberrant Golgi structure through mislocalization of crucial Golgi proteins. In addition, the compromised biosynthetic trafficking seen in some yeast Sec34/35 complex mutants (Wuestehube et al., 1996; Kim et al., 2001) may be a consequence of secondary anterograde trafficking defects arising from primary retrograde trafficking defects (Gaynor and Emr, 1997; Reilly et al., 2001).

Whyte and Munro (2001) suggested that the yeast Sec34/35 complex may be evolutionarily and functionally related to the Sec6/8 complex, also called the exocyst, which has been proposed to tether transport vesicles to the plasma membrane (Grindstaff et al., 1998; Guo et al., 1999). We have found that the mammalian COG and Sec6/8 complexes comigrate during numerous purification steps. Thus, they share many biochemical and biophysical properties, including hydrodynamic size and shape and overall surface charge/hydrophobicity (this study; unpublished data). Also, as noted previously (Walter et al., 1998), both complexes contain eight subunits with very similar molecular weights. However, their appearances in deep etch EM differ. Therefore, further work to elucidate the relationship of these complexes is required.

In summary, mammalian COG and its yeast homologue clearly play important roles in determining the structure and function of the Golgi apparatus and can influence intracellular membrane trafficking. However, their precise mechanism of action remains unknown. This is highlighted by the fact that the yeast Sec34/35 complex’s subunits exhibit numerous genetic interactions both with cellular components proposed to be involved in tethering vesicles to the early Golgi apparatus (VanRheenen et al., 1998, 1999; Kim et al., 1999, 2001; Ram et al., 2002) and with the COPI vesicle coat (Kim et al., 2001; Ram et al., 2002). Genetic and biochemical studies raise the possibility that the COG and Sec34/35 complexes may be directly involved in vesicular membrane transport processes (e.g., vesicle budding, targeting, or fusion reactions). Alternatively, COG may indirectly influence trafficking as a consequence of a direct influence on the structure or activity of one or more compartments of the Golgi apparatus (e.g., potential scaffolding activity).

The characterization of the composition and structure of COG combined with the analysis of COG mutants provides a strong foundation for future studies of the function of this important molecular machine.

Materials and methods

Materials

Antibodies used for immunoblotting (IB) and for immunofluorescence (IF) and their dilutions were as follows: rabbit polyclonal affinity-purified anti-Cog5 (anti–GTC-90) (IB, 1:500–1,000; IF, 1:100; Walter et al., 1998), rabbit polyclonal affinity-purified anti-Cog2 Cpep (anti–lIdcp Cpep) (IB, 1:2,000–3,000; Podos et al., 1994), rabbit polyclonal anti-Cog3 serum (anti–hSec34) (IB, 1:10,000; Suvorova et al., 2001), affinity-purified rabbit anti-Cog3 (anti–lSec34) (IB, 1:3,000; IF, 1:3,000; Suvorova et al., 2001), mouse monoclonal anti-Cog1 (anti–Idlbp) (IB, 1:250–600; IF, 1:100; BD Biosciences), rabbit polyclonal anti-Cog1 (anti–Idlbp) antiserum (IB, 1:3,000), affinity-purified rabbit polyclonal anti-Cog1 (anti–Idlbp) (IF, 1:150, mouse monoclonal anti-Sec8 (IB, 1:2,500; BD Biosciences), mouse monoclonal anti–β-COP (IB, 1:1,000; Sigma-Aldrich), rabbit anti–mannosidase II (IF, 1:2,000; a gift from Kelley Moremen, University of Georgia, Athens, GA), and mouse monoclonal anti–HA-11 (IF, 1:400; Covance).

Dialysis membranes (mol wt cutoff of 12–14 kD) were from BioDesign Inc. The ceramic hydroxyapatite column was from Bio-Rad Laboratories, and all other chromatography materials and secondary antibodies conjugated with HRP for immunoblotting and chemiluminescence were obtained from Amersham Pharmacia Biotech. Compamin was a gift from A. Endo (Tokyo Noda University, Tokyo, Japan). Newborn calf lipoprotein-deficient serum (NCLPDS) and LDL were prepared as previously described (Krieger, 1983). Glutaraldehyde, osmium tetroxide, uranyl acetate, and eponate were obtained from Ted Pella Inc. All other chemicals were purchased from Sigma-Aldrich, unless otherwise noted.

Purification of COG

All procedures were performed at 4°C. Solutions were buffered with 25 mM Tris-HCl, pH 8.0, 1 mM DTT (DT) and contained the indicated amounts of KCl (e.g., 100 mM KCl and glycerol, unless otherwise noted. Bovine brain cytosol was ammonium sulfate precipitated as previously described (Waters et al., 1992). After resuspension of the precipitated proteins and adjustment of the salt concentration to 1M KCl, the sample was chromatographed on butyl-Sepharose. The COG complex was eluted with TD KCl, 10% glycerol. After adding potassium phosphate (KP) to a final con-
centration of 5 mM, the dialyzed sample was chromatographed on a cer-
amic hydroxyapatite column. COG complex was eluted with a KP gradi-
ent and fractions were immediately dialyzed against TD + 100 mM KCl,
10% glycerol in a microdialyzer (GIBCO BRL). The second peak of CoG5
immunoreactivity (Fig. 1 A, peak 2) was then concentrated and loaded onto
a Superose 6 HR10/30 sizing column. Fractions containing COG complex
were pooled and chromatographed on a MiniQ column. An estimated 70
μg of COG complex eluted at ~220 mM KCl in the gradient.

Analytical gel filtration of the two different CoG5-containing complexes
(Fig. 1 B) was performed on a Superose 6 3.2/30 column.

Gel filtration chromatography of COG complex in cell lysates from
CHO cell lines (Fig. 7 B) was performed as previously described (Chatter-
ton et al., 1999).

Mass spectrometry

COG complex (~40 μg) was separated on a 1-mm-thick 7.5% SDS-poly
acrylamide gel. The gel was stained with colloidal Coomassie blue (Invi-
trogen) and destained in water. Four individual bands and two doublets
were excised and subjected to electrospray MS/MS peptide sequencing af-
after in-gel trypsin digestion and HPLC separation (Yates et al., 1999) at the
Harvard Microchemistry Facility.

Deep etch EM of purified COG complex
To visualize single COG complex particles, ~20 μg of purified COG com-
plex (Fig. 2 A, fraction 18) was visualized on mica by quick freeze/deep
etch/rotary shadowing microscopy as previously described (Heuser, 1983).
For glutaraldehyde fixation, the 10 μg/ml COG solution was mixed with a
small volume of 2% glutaraldehyde and incubated for 30 min before mixing
with a suspension of mica flakes. Final anaglyph 3-D images were gener-
ated as described by Heuser (2000).

Transmission EM of cells
Cells were rapidly rinsed with PBS containing 1 mM MgCl₂ and 0.01 mM
CaCl₂, fixed with 2% glutaraldehyde in 0.1 M sodium cacodylate-HCl, pH 7.2,
for 60 min at 4°C, and postfixed with 2% osmium tetroxide in 0.1 M so-
dium cacodylate-HCl for 60 min at 4°C. The cells were harvested by scraping
from the plastic dish and centrifugation at 750 g for 5 min to form a small pel-
et. The pellet was then dehydrated in graded alcohol up to 70% and en-
block stained with 70% alcoholic uranyl acetate for 30 min at 4°C. The sam-
ple was then processed for epon embedding (Vasile et al., 1983). Thin epon
sections were poststained with uranyl acetate and Reynold’s lead citrate and
viewed with a Philips 400 electron microscope operated at 80 kV.

Immunoprecipitation of the COG complex from rat liver cytosol and
a partially purified bovine brain COG complex preparation
For immunoprecipitation, 5 μg of monoclonal anti-CoG1 antibody was added
to 30 μl of partially purified bovine brain COG complex (purified through
the Monq step). For immunoprecipitation with affinity-purified anti-CoG1
antibody, 5 μg of antibody was incubated with 200 μg of antigenic pep-
tide (see below) was added to 400 μg of rat liver cytosol. The samples were ad-
justed to a total of 500 μl with PBS with (for anti-CoG1) or without (for anti-
CoG2) 3% (w/vol) nonfat dried milk and incubated overnight at 4°C. Sub-
sequently, the sample was incubated for 2 h at room temperature with 10
μl of a 50% (vol/vol) slurry of protein A-Sepharose CL-4B in PBS. The
beads were then washed four times with 500 μl PBS with (for anti-CoG1) or
without (for anti-CoG2) 5% (w/vol) nonfat dried milk and once with 500 μl
of PBS. Precipitated proteins were eluted in SDS sample buffer and ana-
yzed by immunoblotting. For anti-CoG2 antigenic peptide competition, the
anti-CoG2 antibody was preincubated for 1 h at room temperature with
10 μg of the COOH-terminal antigenic peptide (Cpep; Podos et al., 1994)
in 100 μl of PBS before addition to the cytosol.

Preparation of the pHM6-CoG7 expression plasmid
Full length CoG7 cDNA was cloned into the pHM6 vector (Roche) with
the restriction enzymes HindIII and KpnI, resulting in the plasmid pHM6-CoG7
 coding for an HA epitope–tagged CoG7.

Mammalian cell culture and transfection
Wild-type CHO, ldlB, ldlC, ldlB[CoG7], and ldlC[CoG2] cells were grown at 37°C
in plastic culture dishes as previously described (Podos et al., 1994; Chatterton et al., 1999). Here we have renamed two stably trans-
fected cell lines to conform to the nomenclature introduced in this paper
(ldlBp is CoG1; ldlCp is CoG2) as follows: ldlB[LDLB] cells (Chatterton et al., 1999) are now called ldlB[CoG1] cells and ldlC[LDLC] cells (Podos et al., 1994) are called ldlC[CoG2] cells. HeLa cells for immunofluorescence
were grown in standard medium on coverslips and transfected with the
calcium phosphate method (Ausubel et al., 1995).

Immunofluorescence microscopy

Cells grown on coverslips were processed at room temperature as follows.
Cells were washed once with PBS and fixed by rinsing and incubating for 25
min with 2% paraformaldehyde (EM Sciences) in 0.1 M NaPO₃, pH 7.2. The
coverslips were then rinsed twice and incubated for 15 min in 0.1 M glycine
in PBS. Cells were then blocked in P-B (0.1% saponin, 1% BSA, 2% normal
good serum (Chemicon)) for 30 min. The coverslips were washed with PBS
followed by a 5-min treatment with 6 μM urea in PBS, four 5-min washes in
PBS, and an additional 45-min incubation in P-B. The treatment with urea
was omitted in the case of double staining with anti–mannosidase II and
anti-HA antibodies. The cells were then incubated for 1 h with primary anti-
bodies (and washed with P-B four times for 5 min each. Secondary antibod-
ies (Alexa488 goat anti–rabbit IgG [H+L] conjugate and Alexa546 or Al-
exa568 goat anti–mouse IgG [H+L] conjugate [Molecular Probes]) diluted
1:750 in P-B were applied for 1 h, and the coverslips were washed with PBS
eight times for 5 min and with water for 5 min. Images were obtained with a
ZEISS LSM 510 laser confocal microscope.

Online supplemental material
For a more detailed description of several methods and the generation of the
anti-CoG1 and anti-CoG2 polyclonal antibodies, see the supplemental mate-
rials located at http://www.jcb.org/cgi/content/full/jcb.200202016/DC1.

We are grateful to Sean Munro (Medical Research Council, Cambridge,
UK), Rachna Ram (MIT), and Chris Kaiser (MIT) for communicating unpublished results and cooperating in naming the complex, Sandy Schmid
(Scripps Research Institute, La Jolla, CA) for encouragement and support,
and Sarah Richman (Princeton University) for the first hint that Sec34/35
and COG are homologous. We thank the Harvard Microchemistry Facility
for expert mass spectrometry and Joe Goodhouse (Princeton University)
and H.R. Horvitz (MIT) for help with confocal fluorescence microscopy.
We are grateful to Kelley Moremen and Juan Bonifacino (National Insti-
tutes of Health, Bethesda, MD) for providing antibodies.

This work was supported by the National Institutes of Health (GM59280
M.G. Waters, GM59115 to M. Krieger, and GM29647 to J.E. Heuser).
