Cortical actin patches are the most prominent actin structure in budding and fission yeast. Patches assemble, move, and disassemble rapidly. We investigated the mechanisms underlying patch actin assembly and motility by studying actin filament ultrastructure within a patch. Actin patches were partially purified from Saccharomyces cerevisiae and examined by negative-stain electron microscopy (EM). To identify patches in the EM, we correlated fluorescence and EM images of GFP-labeled patches. Patches contained a network of actin filaments with branches characteristic of Arp2/3 complex. An average patch contained 85 filaments. The average filament was only 50-nm (20 actin subunits) long, and the filament to branch ratio was 3:1. Patches lacking Sac6/fimbrin were unstable, and patches lacking capping protein were relatively normal. Our results are consistent with Arp2/3 complex-mediated actin polymerization driving yeast actin patch assembly and motility, as described by a variation of the dendritic nucleation model.

Introduction

Budding yeast contain actin binding and regulatory proteins, most of which are found in all eukaryotes, suggesting that fundamental mechanisms of actin dynamics and regulation may be conserved (Pollard and Borisy, 2003). However, the actin concentration is much less in yeast than in vertebrate cells (Nefsky and Bretscher, 1992). The most prominent yeast actin structures are cortical patches (Adams and Pringle, 1984), which have been implicated in endocytosis and cell wall remodeling (Utsugi et al., 2002; Kaksonen et al., 2003). Actin patches are dynamic. They assemble, move, and disassemble within minutes.

Patch formation and movement appear to require actin polymerization nucleated by Arp2/3 complex (Winter et al., 1997). Purified Arp2/3 complex generates end to side branches with a specific angle and polarity (Mullins et al., 1998; Volkmann et al., 2001). Arp2/3 complex branches have been observed in cell extracts and detergent-extracted cultured vertebrate cells (Svitkina and Borisy, 1999; Cameron et al., 2001). In situ cryoEM studies of Dictyostelium revealed branched thin filaments, but filament polarity was not determined and many branch angles were not characteristic of Arp2/3 complex (Medalia et al., 2002).

Actin-based motility can be reconstituted with purified Arp2/3 complex, capping protein, and ADF/cofilin (Loisel et al., 1999). This observation and the biochemical and structural studies above have led to the dendritic nucleation model (Pollard and Borisy, 2003), which is proposed to account for actin-based motility in vertebrate cells at the leading edge and comet tails of pathogens such as Listeria monocytogenes (Loisel et al., 1999). The dendritic nucleation model may apply to yeast actin patches. Activators of Arp2/3 complex appear to direct the growth and maturation of actin patches (Kaksonen et al., 2003). However, although capping protein colocalizes with Arp2/3 complex at sites of actin assembly in most systems (Wear and Cooper, 2004), and capping protein is a yeast actin patch component, yeast strains lacking capping protein are viable, and their actin patches assemble and move (Kim et al., 2004). In addition, cofilin may be unnecessary for patch motility (Lappalainen and Drubin, 1997). Thus, the dendritic nucleation model may not apply to actin patches.

Actin patch assembly and movement in yeast have been well studied by genetic, cell biological, and biochemical approaches. However, a key piece of the puzzle is missing: how are actin filaments in a patch organized? Ultrastructural studies of the yeast actin cytoskeleton have been challenging because of the high density of yeast cytosol. A thin-section
Results and discussion

Purification of actin patches

Actin patches are at the cell cortex, but when yeast are lysed, patches are expelled with the cytoplasm (Fig. 1A). To purify actin patches, we GFP-labeled them and followed them by fluorescence microscopy. Unless stated otherwise, we GFP-labeled the Cap1 subunit of capping protein. GFP-labeled patches in cell lysates did not correlate with any structures observed with DIC or phase contrast optics and were absent in preparations from strains lacking GFP. Actin patches were stable at 4°C in a concentrated cell lysate for >24 h, but disassembled in <2 h at 25°C or when diluted into a variety of buffers. We found that KS buffer, which contains 1 M sorbitol and 0.2 M potassium phosphate, stabilized actin patches over in minutes, we asked if KS stabilized actin filaments. Patches to dilution for hours. Because patches in vivo turn over in minutes, we asked if KS stabilized actin filaments.

Quantitation of filamentous actin in patches was not affected by addition of 5 mM excess to actin subunits. The number and intensity of GFP-labeled patches did not change over 16 h at 4°C and measured the number and fluorescence intensity of GFP-labeled patches with or without 4 mM latrunculin. Latrunculin did not affect the rate of patch disassembly, indicating that the conditions of our protocol, even in the absence of cross-linker, actin patches...
Purified yeast actin patches were not dynamic or turning over. Patches did disassemble if removed from high osmolarity or cold temperature.

To assess the purification, we performed SDS-PAGE on fractions of a purification performed without chemical cross-linker. Coomassie-stained protein profiles of lysed cells, cleared lysate, and all fractions up to I3 were indistinguishable. Actin was the most prominent band in P5, a substantial enrichment. However, most of the P5 bands were also present in I3, showing that the purification was only partial (Fig. 1 E). We also counted the number of GFP-labeled patches and examined the relative amount of actin with Western blots. Actin cofractionated with GFP-labeled patches except for the presence of some actin, presumably free monomers, in the supernatant above fraction I3. The number of Cap1-GFP labeled patches and the amount of actin were enriched ~50-fold and >300-fold, respectively, relative to fraction S1 (Table I). Abp1-GFP was lost from patches to a greater degree than was Cap1-GFP. The enrichment of GFP-labeled patches was significantly higher in cross-linked preparations, although SDS-PAGE and immunoblot analysis of these samples were not possible.

Identification of actin patches in the EM

Even with chemical cross-linker, actin patches were only partially purified, so we needed to identify patches in the EM. We adhered GFP-labeled patches to an EM grid and examined the grid by fluorescence microscopy. The same grid was negative-stained and examined in the EM. Fiducial marks, including grid bars, were used to align brightfield and fluorescence images with low magnification EM images, allowing one to identify GFP-labeled patches unambiguously. Every GFP-labeled patch coincided with a structure in the EM, but only ~10% of negatively stained objects contained GFP (Fig. 2).

Actin patches from chemically cross-linked preparations contained branched networks of thin filaments resembling...
The correlation between filament networks and fluorescent patches was very good. In areas where the negative stain allowed filament visualization, $>95\%$ of fluorescent patches coincided with filament networks, and $>90\%$ of thin filament networks coincided with a fluorescent patch. In addition, the fluorescence intensity correlated with filament network size. Often, proteinaceous material obscured the filaments in a portion of a patch (Fig. 2).

Filaments were less apparent in actin patch preparations purified without chemical cross-linking, even considering the lower yield of patches. These putative patches were predominantly membranous and proteinaceous with a few thin filaments at their periphery. Neither 0.1\% Triton X-100 nor 1 M NaCl treatment increased the appearance of filaments substantially. However, addition of 50 \mu M latrunculin A for 5 min at 25°C, followed by fixation, did produce filamentous networks (Fig. 3). This result is quite surprising, and we do not have a compelling explanation for why latrunculin should have this effect. However, new polymerization should not occur in the presence of latrunculin. Thus, the branched filaments must have been present before the treatment. We do not know if latrunculin affected the network’s organization.

Most filament networks in latrunculin-treated preparations were associated with 1–3 \umu m membranous structures (Fig. 3). In the absence of cross-linker, addition of 0.1–10\% Triton X-100 to cell lysate did not affect GFP-labeled patches; however, patches disappeared when the lysate was centrifuged. Thus, membrane may stabilize some patches to centrifugations. These are a minority of patches because
Cross-linked preparations contained many more fluorescent patches, and few cross-linked patches were associated with membranes in the EM.

**S1 decoration and the branching pattern of actin patch filaments**

We decorated filaments with myosin S1. The patches could not be chemically cross-linked for S1 binding, so latrunculin treatment was used, as described above. The filaments were decorated in a chevron pattern characteristic of actin. At every end to side branch, the daughter filament’s barbed end projected away from the branch point (Fig. 3 C). The angle between the daughter filament and the mother filament segment with the barbed end was $69 \pm 8^\circ$ (mean $\pm$ SD, $n = 18$), the same as $70 \pm 7^\circ$ for branches seen with purified Arp2/3 complex (Mullins et al., 1998; Volkman et al., 2001). Lamellipodia of vertebrate cells contain Arp2/3 complex branches with barbed ends oriented toward the leading edge (Svitkina and Borisy, 1999). The branched filaments in our yeast actin patches showed no linear or radial directionality; the network was isotropic. Negative staining flattens the specimen, so some architectural features may have been lost.

In 11 patches from a cross-linked preparation, patch diameter was $409 \pm 170$ nm (mean $\pm$ SD; range, 150–750), the number of filaments per patch was $85 \pm 46$ (mean $\pm$ SD; range, 18–174), the number of end to side branches per patch was $29 \pm 16$ (mean $\pm$ SD; range, 7–57), and the average filament length was $50 \pm 27$ nm (mean $\pm$ SD; $n = 938$; range, 10–195). A representative analysis of one patch is shown in Fig. 4. The short filament length and degree of branching supports the notion that Arp2/3-based nucleation activity in patches is present as indicated by studies of Arp2/3 mutants (Winter et al., 1997).

We looked for evidence of different populations of patches. In lamellipodia, filaments become longer and less branched over time (Svitkina and Borisy, 1999) so older patches might have longer or less branched filaments. However, the average filament length was uniform (Fig. S2, available at http://www.jcb.org/cgi/content/full/jcb.200404159/DC1), and filament architecture was similar in all patches. Patch diameter, number of filaments, and number of branches correlated significantly (Fig. S2). Thus, patches differed only in size, containing different amounts of branched filament network.

The daughter was more often attached near the middle of the mother filament; 51% of branches were in the middle third of the mother filament, whereas 24–25% occurred in each distal third ($n = 91$, $P < 0.1$ by $\chi^2$). The daughter filament length was $66 \pm 38\%$ of the entire length of its mother filament.

**Analysis of mutant patches**

Yeast Sac6/fimbrin bundles actin filaments in vitro, localizes to patches in vivo, and is present at a 1:10 molar ratio with actin (Goodman et al., 2003). However, bundles were not seen in patches from wild-type cells. Purified yeast Sac6/fimbrin also stabilizes actin filaments against depolymerization (Goode et al., 1999), and sac6Δ mutant strains have synthetic defects with many actin-regulating proteins (Goodman et al., 2003). Therefore, we asked if Sac6 was important for patch

---

**Figure 4. Actin patches from cross-linked preparations.** (A) The branched filament network of a typical actin patch. Arrowheads mark some branches. (B) A graphical representation (bottom) of the actin filaments in another typical patch (top). Filament length and branching were quantitated for this patch, as indicated by the green lines and red dots, respectively. Strain YJC1453.
Unexpectedly, actin patches purified from a strain lacking Sac6/fimbrin. Actin patches from a sac6 null strain disassembled within 20 min of cell lysis in the absence of chemical cross-linker, even in the presence of 1 M sorbitol. Wild-type patches were stable for >24 h under these conditions. Even sac6Δ patches cross-linked within 5 min of cell lysis were significantly dimmer than patches in vivo. We identified purified sac6Δ patches, or patch fragments, in the EM by correlation microscopy. They were smaller in diameter (70–290 nm, n = 10) than wild-type patches (150–750 nm) with proportionately fewer filaments and branches. However, the density and architecture of the network was normal (Fig. 5). Therefore, Sac6/fimbrin is important for patch stability, possibly stabilizing filaments by side-binding, but is not essential for the general architecture.

Capping protein has a central role in the dendritic nucleation model, localizes to actin patches in yeast (Kim et al., 2004), and increases branching by Arp2/3 complex in actin polymerization. The dendritic nucleation model, and yeast actin patches, were smaller in diameter (70–290 nm, n = 10) than wild-type patches (150–750 nm) with proportionately fewer filaments and branches. However, the density and architecture of the network was normal (Fig. 5). Therefore, Sac6/fimbrin is important for patch stability, possibly stabilizing filaments by side-binding, but is not essential for the general architecture.

The dendritic nucleation model and yeast actin patches
The dendritic nucleation model applies only in part to the assembly and motility of yeast actin patches. The model predicts a highly branched filament network with branches characteristic of Arp2/3 complex, which we observed here. The model is also supported by previous studies showing Arp2/3’s importance for patch assembly and motility (Winter et al., 1997). On the other hand, the model predicts an important role for capping protein, and the filament architecture of patches lacking capping protein was normal here. Moreover, capping protein and coflin are not necessary for normal patch movement in vivo (Lappalainen and Drubin, 1997; Kim et al., 2004). Perhaps yeast cytoplasm in general lacks free barbed ends that must be capped to “funnel” actin polymerization to the patch. Indeed, free barbed ends are detected only at actin patches in permeabilized cell assays (Li et al., 1995; Kim et al., 2004).

Materials and methods
Yeast strains
Cap1-GFP was expressed in the MATa Research Genetics/Invitrogen Sac6::His3 (strain number 14063), sporeulated, and tetrad dissected, resulting in the strain YJC3580 (MATa CAP1-GFP HIS3 sac6Δ:KanR his3Δ ura3Δ leu2Δ). The presence of Cap1-GFP was verified visually by fluorescence microscopy as well as by PCR across the junction of Cap1 and GFP. The sac6Δ disruption was confirmed by sequencing the upstream tag. A haploid cap1Δ Sac6-GFP strain, YJC3481 (MATa SAC6-GFP HIS3 cap1Δ:KanR his3Δ ura3Δ leu2Δ lys2Δ), and a homozygous diploid Cap1-GFP strain, YJC1453 (MATa CAP1-GFP HIS3/CAP1-GFP HIS3 his3Δ his3Δ ura3Δ leu2Δ), were described previously (Karpova et al., 2000; Kim et al., 2004).

Actin patch purification
Yeast were grown in 1 liter of YPD to an OD600 of ~1.0. Cells were washed twice with KS (200 mM potassium phosphate, pH 7.0, 1 M sorbitol), suspended in 1 ml KS, 0.1 M β-mercaptoethanol, and 0.6 mg/ml zymolyase 20T (ICN Biomedicals), and incubated for 1 h at 37°C. Spheroplasts were washed twice with KS, suspended in 1 ml of 2% Nonidet P-40 solution, and washed twice with KS (200 mM potassium phosphate, pH 7.0, 1 M sorbitol), washed twice with KS, 0.1 M β-mercaptoethanol, and 0.6 mg/ml zymolyase 20T (ICN Biomedicals), and incubated for 1 h at 37°C. Spheroplasts were washed twice with KS, incubated for 1 h at 37°C, and washed twice with KS (200 mM potassium phosphate, pH 7.0, 1 M sorbitol). After 20 min of cell lysis in the absence of chemical cross-linker, even in the presence of 1 M sorbitol. Wild-type patches were stable for >24 h under these conditions. Even sac6Δ patches cross-linked within 5 min of cell lysis were significantly dimmer than patches in vivo. We identified purified sac6Δ patches, or patch fragments, in the EM by correlation microscopy. They were smaller in diameter (70–290 nm, n = 10) than wild-type patches (150–750 nm) with proportionately fewer filaments and branches. However, the density and architecture of the network was normal (Fig. 5). Therefore, Sac6/fimbrin is important for patch stability, possibly stabilizing filaments by side-binding, but is not essential for the general architecture.

Capping protein has a central role in the dendritic nucleation model, localizes to actin patches in yeast (Kim et al., 2004), and increases branching by Arp2/3 complex in actin polymerization reagents in vitro (Blanchoin et al., 2000). Unexpectedly, actin patches purified from a cap1 null strain, with Sac6-GFP, showed a qualitatively normal organization of actin filaments, including filament length and branching, relative to wild-type patches.

Fluorescence microscopy and correlation of images
GFP-labeled actin patches were viewed in whole yeast and cell extracts using a HeQ FITC filter cube and a cooled CCD camera as described previously (Karpova et al., 2000). Cell lysates and spheroplasts were stained with 660 nM rhodamine-phalloidin (Fluka) after fixation with 0.1% glutaraldehyde, and the spheroplasts were permeabilized with 0.1% Triton X-100. Fluorescence intensity was quantitated with NIH Image.

For correlation microscopy, EM grids with GFP-labeled patches were viewed in whole yeast and cell extracts using a HeQ FITC filter cube and a cooled CCD camera as described previously (Karpova et al., 2000). Cell lysates and spheroplasts were stained with 660 nM rhodamine-phalloidin (Fluka) after fixation with 0.1% glutaraldehyde, and the spheroplasts were permeabilized with 0.1% Triton X-100. Fluorescence intensity was quantitated with NIH Image.

Light and EM fields were correlated with London finder grids or imperfections in standard grids (Electron Microscopy Sciences). Low magnification, $\times$1500, EM images were aligned with the light images in Adobe Photoshop. Multiple patches were identified in the EM within 1–2 $\mu$m of their predicted location, leading to a refined alignment at a precision of 100–200 nm over the entire $40 \times 60$ $\mu$m field. Patches from haploid and diploid strains were similar.

Online supplemental material

Online supplemental material includes protein methods and two figures. Fig. S1 shows actin depolymerization after dilution into KS or other buffers. Fig. S2 shows which actin patch characteristics are correlated. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.200404159/DC1.

Supplemental materials and methods

Protein analysis
Protein was quantified with the BCA kit (Pierce Chemical Co.). 10% SDS-PAGE acrylamide gels were prepared as described, stained with Coomassie or transferred to nitrocellulose in the presence of 0.1% SDS and 20% methanol. Gels were probed with a 1:5,000 dilution of G2 goat anti-actin serum (Karpova et al., 1993) and an HRP-conjugated secondary antibody (Sigma-Aldrich). Densitometry was performed on scanned images with NIH Image.

Actin depolymerization assays were performed essentially as described previously (Wear et al., 2003). Actin was purified from porcine skeletal muscle and pyrene labeled. 50 μl aliquots of 5 μM actin, 20% pyrene labeled, were polymerized for >2 h at RT in the presence of 10 mM imidazole, pH 7.0, 50 mM KCl, 2 mM MgCl₂, and 1 mM EGTA. One reaction was added to 2.45 ml of 10 mM imidazole, pH 7.0, with or without 1 M sorbitol and/or 0.2 mM potassium phosphate. Pyrene fluorescence was detected and the fluorescence values were normalized to the appropriate buffer.

Myosin S1 preparation and use
Myosin S1 was prepared by an adaptation of the protocol described in Margossian and Lowey (1982). Myosin was extracted from fresh porcine skeletal muscle and stored as a 50% ammonium sulfate precipitate at 4°C. 5–10 mg of myosin was digested with 50 nM papain for 7 min at 25°C, and the digestion stopped by 1 mM iodoacetamide. The reaction was dialyzed into 50 mM Tris, pH 6.8, 2 mM MgCl₂, 2 mM DTT for 2 h, and centrifuged at 40,000 g for 30 min. The supernatant was collected and diluted 64-fold for labeling. Grids with actin patch samples were incubated with latrunculin A as described above, washed twice with KS, and incubated with the diluted S1 for 5 min before fixing and processing as described above.
