HIV-1 Nef disrupts MHC-I trafficking by recruiting AP-1 to the MHC-I cytoplasmic tail

Jeremiah F. Roeth, Maya Williams, Matthew R. Kasper, Tracey M. Filzen, and Kathleen L. Collins

To avoid immune recognition by cytotoxic T lymphocytes (CTLs), human immunodeficiency virus (HIV)-1 Nef disrupts the transport of major histocompatibility complex class I molecules (MHC-I) to the cell surface in HIV-infected T cells. However, the mechanism by which Nef does this is unknown. We report that Nef disrupts MHC-I trafficking by rerouting newly synthesized MHC-I from the trans-Golgi network (TGN) to lysosomal compartments for degradation. The ability of Nef to target MHC-I from the TGN to lysosomes is dependent on expression of the μ1 subunit of adaptor protein (AP) AP-1A, a cellular protein complex implicated in TGN to endosomal pathways. We demonstrate that in HIV-infected primary T cells, Nef promotes a physical interaction between endogenous AP-1 and MHC-I. Moreover, we present data that this interaction uses a novel AP-1 binding site that requires amino acids in the MHC-I cytoplasmic tail. In sum, our evidence suggests that binding of AP-1 to the Nef–MHC-I complex is an important step required for inhibition of antigen presentation by HIV.

Introduction

The human immunodeficiency virus (HIV) establishes a chronic infection in T lymphocytes by evading the host immune response. To prevent recognition and killing by host cytotoxic T lymphocytes (CTLs), HIV reduces the cell surface expression of major histocompatibility complex class I molecules (MHC-I) (Schwartz et al., 1996), which are needed to present antigenic peptides to CTLs. The HIV Nef protein is required for the reduced MHC-I cell surface expression (Schwartz et al., 1996) and to thereby protect HIV-infected primary T cells from anti-HIV CTLs (Collins et al., 1998).

HIV-1 Nef is a 27–34-kD multifunctional protein that has no apparent enzymatic activity and is thought to function by acting as an adaptor protein (AP). Consistent with this, Nef binds to cytoplasmic tail domains (Harris and Neil, 1994; Greenway et al., 1995; Grzesiek et al., 1996; Rossi et al., 1996; Schaefer et al., 2000; Williams et al., 2002), and contains a number of potential protein–protein interaction domains that are required either for MHC-I or CD4 downmodulation. An NH2-terminal α helical domain, an acidic domain and a polyproline repeat are all required for MHC-I downmodulation (Greenberg et al., 1998b; Mangasarian et al., 1999). In contrast, dileucine and diacidic motifs within Nef are necessary for removal of cell surface CD4 (Aiken et al., 1994; Greenberg et al., 1998b).

Thus far, Nef has been shown to downmodulate all MHC-I HLA-A and HLA-B allotypes. However, Nef does not downmodulate MHC-I HLA-C and HLA-E (Le Gall et al., 1998; Cohen et al., 1999). This selective downmodulation results from amino acid sequence variation in the Nef binding domain within the cytoplasmic tails of these molecules (Williams et al., 2002). Because HLA-C and HLA-E are known to inhibit natural killer cell lysis, it has been proposed that maintenance of their cell surface expression may allow survival of the infected cell (Le Gall et al., 1998; Cohen et al., 1999).

The current model for how Nef affects CD4 cell surface expression is that Nef binds to the CD4 cytoplasmic tail and links it to cellular trafficking proteins that accelerate its endocytosis. Indeed, Nef is known to interact with a number of proteins that regulate intracellular trafficking. For example, Nef interacts with the heterotetrameric clathrin APs (AP-1, AP-2, and or AP-3; Bresnahan et al., 1998; Greenberg et al., 1998a; Le Gall et al., 1998; Piquet et al., 1998; Craig et al., 2000; Erdtmann et al., 2000; Janvier et al., 2003a,b), through the same dileucine motif that is needed for CD4 downmodulation (Bresnahan et al., 1998; Greenberg et al., 1998a; Craig et al., 2000; Janvier et al., 2003a,b).

The adaptin complexes (Robinson and Bonifacino, 2001; Traub, 2003; Robinson, 2004) are each composed of four subunits; two large subunits (β1, β2, β3 plus γ, α, or δ), medium...
subunit (μ1A, μ1B, μ2, μ3) and one small subunit (σ1, σ2, σ3) for AP-1 (A or B), AP-2 and AP-3, respectively. There is evidence that all of these complexes sort proteins by binding recognition sequences in their cytoplasmic tails and linking them to clathrin. AP-1 is localized to the TGN and endosomes. Thus, it is thought to be important for trafficking between these compartments (Doray et al., 2002; Waguri et al., 2003), and for eventual sorting of some proteins (e.g., lysosomal hydrolases) to the lysosomes. AP-3 is localized to endosomes (Peden et al., 2004) and is needed for proper targeting of other proteins (e.g., lysosome-associated membrane protein [LAMP-1]) to lysosomes. Finally, AP-2 is localized to the cell surface and plays a role in endocytosis (Traub, 2003). Thus, one model is that Nef-dependent CD4 endocytosis occurs via recruitment of AP-2 through Nef’s dileucine motif. Nef-dependent CD4 endocytosis may additionally require interaction with a subunit of the vacuolar ATPase (Lu et al., 1998), which may indirectly promote an association of Nef with AP-2 (Geyer et al., 2002). However, the mechanistic details of how interactions of Nef with various adaptin molecules accelerate CD4 endocytosis and degradation are not well understood.

There is increasing evidence that Nef disrupts MHC-I cell surface expression by a different mechanism than it uses to downmodulate CD4. The diacidic motif needed for Nef to interact with the vacuolar ATPase to promote CD4 down-regulation is not required for Nef to disrupt MHC-I trafficking (Greenberg et al., 1998b; Lu et al., 1998). In addition, the dileucine motif within Nef that is required for Nef to directly bind adaptin complexes is also dispensable (Greenberg et al., 1998b; Mangasarian et al., 1999). Moreover, in HIV-infected T lymphocytes and astrocytic cells, the primary effect of Nef on MHC-I is to disrupt its transport to the cell surface rather than to promote its endocytosis (Swann et al., 2001; Kasper and Collins, 2003). The molecular mechanism underlying this effect of Nef is unknown.

To determine how Nef disrupts the transport of MHC-I to the cell surface, we used biochemical and cell biological approaches to examine MHC-I trafficking in Nef-expressing T cells. We found that Nef redirected MHC-I from the TGN to lysosomes. Moreover, we demonstrated that the AP, AP-1, which is required for proper sorting of lysosomal hydrolases from the TGN to lysosomes, was required for Nef to disrupt MHC-I trafficking. Finally, in HIV-infected primary T cells, we found that Nef stabilized an interaction between MHC-I and AP-1. This interaction used a novel domain that required sequences from the NH₂-terminal α helix of Nef and from the MHC-I cytoplasmic tail.

Results

To perform large scale biochemical experiments to examine the effects of Nef on MHC-I trafficking in T cells, we developed a system that permitted transient, uniform, expression of Nef in T cells. This was accomplished by using a replication-defective adenoviral vector expressing HIV-1 Nef, which disrupts MHC-I transport in a manner that is indistinguishable from HIV (Kasper and Collins, 2003). In addition, to specifically detect an allotype of MHC-I that is responsive to Nef, we attached an HA tag to the NH₂-terminal extracellular domain of HLA-A2. Based on a number of biochemical measurements, the tagged molecule was folded properly, matured through the secretory pathway normally, and was equally responsive to HIV-1 Nef (Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200407031/DC1).

Trafficking of MHC-I in Nef-expressing T cells

It has been previously shown that Nef does not affect the transport of MHC-I into the medial Golgi apparatus (Schwartz et al., 1996), but does inhibit its transport to the cell surface (Kasper and Collins, 2003). To further define where in the secretory pathway Nef exerts its effects, we asked whether MHC-I was transported normally into the TGN. This was accomplished by monitoring the rate at which HLA-A2 acquired sialic acid residues in this compartment, which can be measured by testing sensitivity to neuraminidase digestion. We detected sialylation of HLA-A2 as a slight increase in HLA-A2 molecular weight (Fig. 1 A, lanes 4 and 7) that was eliminated by neuraminidase treatment (Fig. 1 A, lanes 5 and 8). Based on these data (quantified in Fig. 1 B), Nef does not delay the transport of HLA-A2 into the TGN. As a control, we also confirmed the previously published observation that Nef does not affect transit into the medial Golgi (Schwartz et al., 1996), as assessed by sensitivity to endoglycosidase H (endo H) digestion (Fig. 1, A and B).

HIV-1 Nef causes HLA-A2 to be degraded in lysosomal compartments

There is consensus that Nef causes the accumulation of MHC-I in the TGN of multiple non-T cell lines (Schwartz et al., 1996; Greenberg et al., 1998b; Le Gall et al., 1998; Piquet et al., 2000; Swann et al., 2001; Blagoveschenskaya et al., 2002). However, it is controversial as to whether MHC-I is ultimately targeted to other organelles in which it is degraded at an accelerated rate (Schwartz et al., 1996; Blagoveschenskaya et al., 2002; Williams et al., 2002). In agreement with other studies performed in T cells (Schwartz et al., 1996), we found that Nef expression accelerated the degradation of mature, endo H resistant HLA-A2, but did not affect the stability of immature, endo H-sensitive molecules (Fig. S2, available at http://www.jcb.org/cgi/content/full/jcb.200407031/DC1). In addition, we found that two inhibitors of lysosomal protein degradation, ammonium chloride and bafilomycin A1, blocked HLA-A2 degradation. Whereas, lactacystin, a proteasome inhibitor, had no effect on HLA-A2 degradation (Fig. 1 C). Thus, after reaching the TGN, HLA-A2 appears to be targeted for lysosomal degradation in Nef-expressing T cells.

To provide supporting evidence that MHC-I is ultimately targeted to lysosomes, we examined the colocalization of HLA-A2 with LAMP-1, a marker of lysosomal compartments (Fig. 1 D). In T cells expressing Nef, we observed a very small amount of colocalization of HLA-A2 with LAMP-1 (Fig. 1 D, 10). The majority colocalized with markers of the TGN (not depicted). However, when lysosomal degradation was inhib-
ited by treatment of cells with bafilomycin A1, the amount of HLA-A2 colocalizing with LAMP-1 dramatically increased in Nef-expressing cells (Fig. 1 D, compare 10 with 12). These data support the model that MHC-I is ultimately directed to lysosomal compartments in Nef-expressing T cells, where it is rapidly degraded.

Nef targets HLA-A2 to lysosomes using an AP-1A-dependent pathway

Transport of lysosomal hydrolases and LAMP-1 to the lysosomes is known to require the APs AP-1 and AP-3. Interestingly, both of these adaptors are known to interact with HIV-1 Nef. Therefore, to explore a possible requirement for these complexes, we transfected cells with siRNAs directed at the $\mu$ subunit of AP-1A and AP-3. As shown in Fig. 2 (A and B), we were able to reduce expression of these molecules in both astrocytic cells and T cells. The effect was more dramatic in astrocytic cells, probably because we were able to transfect them more efficiently than T cells.

In both cell types, we found that inhibiting the expression of AP-1A, but not that of AP-3, reduced the effect of Nef on MHC-I cell surface expression (Fig. 2, C and D). In addition,
AP-1A expression was required for HLA-A2 degradation (Fig. 2 E). However, reducing the expression of μ1A and μ3 did not affect Nef’s ability to downmodulate CD4 (Fig. 2, C and D), nor did it affect Nef expression (Fig. 2, A, B, and E). These results suggest that AP-1A expression is specifically required for Nef to disrupt MHC-I cell surface expression and to target it for degradation.

**Nef promotes the formation of a complex containing MHC-I and AP-1**

To determine whether Nef functions as an AP linking MHC-I to AP-1, we immunoprecipitated endogenous HLA-A2 from HIV-infected primary T cells and then immunoblotted for Nef and for endogenous subunits of AP-1. As expected, we detected Nef protein coprecipitating with HLA-A2 (Fig. 3 A). In addition, we also detected the μ and γ subunits of AP-1 coprecipitating with HLA-A2. This result is particularly striking because only ~25% of the primary T cells were infected in this experiment. The interaction was highly specific based on the fact that the related AP, AP-3, did not coprecipitate with HLA-A2 (Fig. 3 B). Thus, these studies strongly indicate that Nef promotes the formation of a complex containing MHC-I and AP-1.
AP-1 binds to the Nef-MHC-I complex in a dileucine-independent manner

Previous studies that have examined the direct interaction of Nef with AP-1 have found that it depends on the Nef dileucine motif (Bresnahan et al., 1998; Craig et al., 2000; Janvier et al., 2003a,b). However, we found that the dileucine motif was not needed for coprecipitation of AP-1 with MHC-I in CEM T cells treated with adeno-Nef (Fig. 4 A) or HIV (Fig. S3, available at http://www.jcb.org/cgi/content/full/jcb.200407031/DC1). These data are consistent with the fact that the dileucine motif is not necessary for disruption of MHC-I trafficking (Greenberg et al., 1998a; Mangasarian et al., 1999), and suggests that there is an alternative AP-1 binding site in the Nef–MHC-I complex.

To rule out the possibility that the interaction we observed was nonspecific, and to verify that it was dependent on Nef do-

Figure 3. Nef expression results in coprecipitation of AP-1 with HLA-A2. [A] HLA-A2–primary human T cells or control CEM-SS cells that did not express HLA-A2 (Ctrl) were transduced with an HIV molecular clone expressing Nef (nef), or a matched control HIV that did not express Nef (f). Cells were harvested, and HLA-A2 was immunoprecipitated as described in Materials and methods. Proteins that coprecipitated with HLA-A2 were detected by Western blotting as indicated. Western blots of protein inputs are also shown as a control for relative protein levels in each sample before immunoprecipitation (Input Controls). Results are typical of two independent experiments. [B] AP-3 does not coprecipitate with HLA-A2. CEM-SS cells (lanes 1 and 4) or CEM HA-HLA-A2 cells (lanes 2, 3, 5, and 6) were infected with HIV, and HLA-A2 was recovered by immunoprecipitation as described in Materials and methods. Coprecipitating proteins were detected by Western blotting (lanes 1–3). A fraction of the protein input before immunoprecipitation was also analyzed to ensure similar protein expression levels (lanes 4–6). Western blots of δ-adaptin (AP-3) and γ-adaptin (AP-1) were performed simultaneously using the same antibody concentrations. Apparent molecular masses of protein standards are denoted in kilodaltons on the left.

Figure 4. Analysis of MHC-I and Nef domains that contribute to AP-1 recruitment. [A] Recruitment of AP-1 requires an intact Nef–MHC-I complex and is independent of the dileucine motif in Nef. CEM-SS cells (lane 1) or CEM HA-HLA-A2 cells (lanes 2–5) were transduced with the indicated adenoviral vector. The cells were harvested at 72 h and subjected to the coimmunoprecipitation assay. Cells were transduced with each adenovirus to achieve equivalent Nef expression levels (Input Controls): wild-type NL4-3 Nef (MOI = 25); NL4-3 Nef with a NH2-terminal deletion (V10E, MOI = 300); HXB Nef with a mutation in the dileucine motif (LL164,165AA, MOI = 25). (As shown, HXB Nef migrates more slowly on SDS PAGE than NL4-3 Nef. Wild-type HXB Nef and HXB NefLL164,165AA are directly compared in Fig. S3.) All results are typical of at least two independent experiments. [B] HLA-A2 tyrosine 320 (Y320) is required for efficient Nef binding, AP-1 recruitment, and targeting for degradation. CEM-SS (lanes 1 and 2), CEM HA-HLA-A2 (lanes 3 and 4), or CEM cells expressing the MHC-I mutant, HA-HLA-A2 Y320A (lanes 5 and 6), were transduced with a control (−) or Nef-expressing adenovirus (+). At 72 h after transduction, HLA-A2 immunoprecipitations were recovered and analyzed by Western blotting as described in Fig. 3.
mains important for MHC-I trafficking to lysosomes, we asked whether AP-1 would coprecipitate with MHC-I in cells expressing a Nef mutant (V10E/H900417-26) that was unable to affect MHC-I trafficking and to bind MHC-I (Mangasarian et al., 1999; Williams et al., 2004). As shown in Fig. 4 A, we found that AP-1 did not coprecipitate with HLA-A2 under these conditions.

In addition, we asked whether AP-1 would coprecipitate with an HLA-A2 mutant lacking a tyrosine residue at position 320 that is necessary for responsiveness to Nef (Greenberg et al., 1998b; Le Gall et al., 1998). As shown in Fig. 4 B, this mutant was expressed well (Fig. 4 B, input controls, bottom). However, it was resistant to Nef-dependent MHC-I degradation, coprecipitated Nef less efficiently, and was defective in AP-1 recruitment (Fig. 4 B). Thus, these studies indicate that coprecipitation of AP-1 with HLA-A2 in Nef-expressing cells was highly specific and depended on amino acid sequences in Nef and MHC-I that are functionally important for Nef’s effects on MHC-I cell surface expression.

Recruitment of AP-1 requires both the cytoplasmic tail of HLA-A2 and the NH2-terminal α-helix in Nef

The domains of HIV Nef specifically involved in MHC-I trafficking have been well characterized. It is known that disruption of Nef’s NH2-terminal α-helix by deletion (V10E/Δ17-26) or point mutation (M50A), mutation of an acidic cluster (E62,65Q), or mutation of a polyproline repeat (P72/75/78A) specifically affects this activity (Greenberg et al., 1998b; Mangasarian et al., 1999). We have recently reported that each of these mutants fails to coprecipitate with MHC-I (Williams et al., 2004) and thus binding to MHC-I may be the primary role of these domains. However, it is also possible that one or more of these domains plays an additional role. To determine whether any of these domains might also be involved in AP-1 recruitment directly, we bypassed the requirement for Nef binding by directly fusing Nef to the COOH terminus of the HLA-A2 cytoplasmic tail (A2/Nef; Fig. 5 A). As expected, Nef was able to reduce the cell surface expression of HLA-A2 in cis (Fig. 5 B, left), and to promote its colocalization with markers of the Golgi apparatus (Fig. 5 C). In addition, the A2/Nef fusion protein was able to efficiently coprecipitate AP-1 from T cell lysates in a manner that was independent of the Nef dileucine motif (Fig. 6 A). However, the fusion protein was not capable of reducing MHC-I surface expression in trans (Fig. 5 B, right). Thus, A2/Nef was a useful reagent to explore which amino acids in Nef and MHC-I were important for AP-1 recruitment to the Nef–MHC-I complex.

As shown in Fig. 6 A, these studies revealed that mutation of amino acids in the NH2-terminal α-helix (A2/V10E/Δ17-26 and A2/M50A) inhibited coprecipitation of AP-1 with the fusion protein. In contrast, disruption of the acidic (A2/E62,65Q) and polyproline (A2/P72,75,78A and A2/P75,78A) domains in Nef had no effect (Fig. 6 A and B). Surprisingly, deletion of the HLA-A2 cytoplasmic tail (A2/ΔTail/Nef) or mutation of tyrosine 320 in the HLA-A2 cytoplasmic tail (A2Y320A/Nef) also
dramatically inhibited coprecipitation of AP-1 by the fusion protein (Fig. 6 C). Thus, sequences in the Nef NH₂-terminal helix as well as in the HLA-A2 cytoplasmic tail are necessary to create a functional AP-1 binding site.

**Discussion**

In sum, we have found that in T cells, Nef disrupts MHC-I trafficking after it reaches the TGN to prevent MHC-I cell surface expression and to promote its degradation in lysosomes. RNAi treatment of Nef-expressing T cells and astrocytic cells revealed that this activity of Nef required the expression of AP-1A, but not AP-3. The requirement for AP-1A was further supported by the fact that we were able to isolate complexes containing MHC-I and AP-1 from Nef-expressing, HIV-infected primary T cells. The dileucine motif in Nef, which is necessary for Nef to directly bind AP-1 in other assay systems, was not needed for AP-1 to bind the Nef–MHC-I complex, suggesting an alternative means of association. Interestingly, when Nef was fused to HLA-A2, AP-1 was only recruited when the NH₂-terminal α helical domain of Nef was intact and when a full-length, wild-type HLA-A2 cytoplasmic tail was present. Thus, amino acids within both Nef and MHC-I were necessary to create a binding site for AP-1 in the Nef–MHC-I complex.

The normal function of AP-1 is to sort proteins, such as lysosomal enzyme receptors, at the TGN by linking clathrin to the cytoplasmic tails of cargo (for review see Dell’Angelica and Payne, 2001; Robinson and Bonifacino, 2001; Traub, 2003; Robinson, 2004). For example, the mannose 6-phosphate receptor (MPR), which binds soluble lysosomal enzymes, is sorted at the TGN by AP-1. It is then transported in vesicles to endosomes where the enzymes dissociate and are carried to the lysosomes. The MPRs are then recycled back to the TGN to transport more cargo. Thus, Nef-induced AP-1 binding of MHC-I would be expected to promote TGN accumulation and/or targeting of MHC-I into the endolysosomal pathway (Fig. 7).

Using the yeast two hybrid system (Le Gall et al., 1998; Piguet et al., 1998; Craig et al., 2000; Erdtmann et al., 2000; Janvier et al., 2003b), GST-Nef pull-downs (Bresnahan et al., 1998; Le Gall et al., 1998; Piguet et al., 1998; Janvier et al., 2003a) or overexpression of a Nef-CD8 chimera in 293 cells (Bresnahan et al., 1998), a number of investigators have found that the HIV-1 Nef protein interacts with adaptin subunits and whole adaptin complexes. A consensus binding domain for adaptin protein binding (D/EXXXLL) (Bonifacino and Traub, 2003) can be found in Nef and this motif is required for GST-Nef to pull down AP-1 complexes from mammalian cell lysates (Bresnahan et al., 1998). In addition, the leucine residues in this motif are required for Nef to down-modulate CD4, but not MHC-I (Greenberg et al., 1998a; Man...
gasarian et al., 1999). Thus, the dileucine-dependent binding to adaptins appears to be important for Nef’s effects on CD4.

Our data showing that the dileucine motif is not required for Nef to promote an interaction between HLA-A2 and AP-1 indicates that there is an alternative binding site for AP-1 in the Nef–MHC-I complex. It should be noted that there is evidence for a second AP-1 binding site within Nef that is active in yeast two hybrid systems (Craig et al., 2000; Erdtmann et al., 2000). However, existing data suggest that this motif is not able to support corecruitment of AP-1 with Nef in mammalian systems (Bresnahan et al., 1998; Janvier et al., 2003a). These data can be explained by our results showing that AP-1 recruitment to HLA-A2 in Nef-expressing cells appeared to result from the creation of a new binding site for AP-1 that was only active when Nef was bound to wild-type MHC-I.

The MHC-I cytoplasmic tail itself does not contain a consensus AP-1 binding site (D/EXXXLL or YXXΦ) (Bonifacio and Traub, 2003). However, the tyrosine residue at position 320 (Y320) that we show is necessary for Nef to recruit AP-1, is also required for the normal targeting of MHC-I to endolysosomal compartments in dendritic cells (Lizée et al., 2003). The mechanism by which MHC-I is normally targeted to these compartments is unknown, and it is interesting to speculate that this motif may be taking advantage of an existing pathway for MHC-I trafficking that is normally only active in certain cell types.

Previous studies describing the mechanism of Nef’s effects on MHC-I have focused on the ability of Nef to accelerate MHC-I endocytosis, rather than on the TGN to lysosomal pathway we describe (Greenberg et al., 1998b; Le Gall et al., 1998, 2000; Piguet et al., 2000). However, it is interesting to speculate that in these cell types Y320 recruits an AP-1, such as AP-1, that targets MHC-I to the endolysosomal compartment. Thus, Nef may be taking advantage of an existing pathway for MHC-I trafficking that is normally only active in certain cell types.

In sum, our results indicate that in T cells, the primary effect of Nef on MHC-I is to promote TGN retention and to ultimately direct MHC-I to lysosomes. We have provided evidence that Nef accomplishes this by acting as an AP, which stabilizes a physical interaction between AP-1 and MHC-I in these target MHC-I into the endolysosomal pathway. These results have important implications for understanding HIV disease pathogenesis and for possible pharmaceutical approaches in combating the development of AIDS.

Materials and methods

Cell culture

CEM T cell lines were maintained in R10 (RPMI supplemented with 10% FBS, 10 mM Heps, 2 mM penicillin, streptomycin, and penicillin (P/S/G). The astrocytic cell lines stably expressing CD4 were maintained in DMEM supplemented with 10% FBS and P/S/G. Stable Nef and CEM T cell lines were generated by transduction with MSCV retroviral constructs pseudotyped with VSV-G as described previously (Kasper and Collins, 2003). Primary T lymphocytes were isolated from buffy coats as described previously (Collins et al., 1998).

DNA constructs

A nine-amino acid HA epitope tag (YPDYDVPDYA) was added to the NH2 terminus of HLA-A2 and HLA-B71 (just after the leader sequence cleavage site and before the N-terminus; Swann et al., 2001) using the following primers and HLA-A2 Y 320A (Swann et al., 2001) using the following primers: forward primer, 5′-GGGATCCTCTCAGAATCTCCTCAGACCAGCAGGAG-3′; reverse primer, 5′-TTCCCGGCGCATGTCGTTGCAGTCTACAGGTCACCCGCGGCGAC-GTCTCCGGT-3′. The PCR product was then digested with EcoRI and NdeI and subcloned into a shuttle vector (New England Biolabs, Inc.). Next, the following primers were used to amplify the 3′ region of HLA-A2 and HLA-B71: HLA-A2 forward primer, 5′-GAATTCATGATCCGATGTGC-3′; HLA-B71 forward primer, 5′-GCGTCTCGAAGCTCTGGAACGACGACCATCT-3′; HLA-A2 reverse primer, 5′-CCGTCGACTGATCCACTTACACATGC-3′; HLA-B71 reverse primer, 5′-CTGGCCCGGCTTCCACTCCATCAT-3′; and mutant reverse primer, 5′-CTGGCCCGGCTTCCACTCCATCAT-3′. The resulting PCR products were digested with NdeI and EcoRI and cloned into the same sites in the retroviral shuttle vector HA-HLA-A2. MSCV HA-HLA-A2 Y320A was cloned by amplifying a portion of HLA-A2 Y320A (Swann et al., 2001) using the following primers: forward primer, 5′-CCGAGCCTAGACACCAAGCAAGCGCGAAG-3′; reverse primer, 5′-CCGTCGACTGATCCACTTACACATGC-3′; and mutant reverse primer, 5′-CCGTCGACTGATCCACTTACACATGC-3′. The vector was then digested with XbaI and HpaI, and was ligated into the same sites in the retroviral shuttle vector HA-HLA-A2. MSCV HA-HLA-A2 Y320A was cloned by amplifying a portion of the wild-type sequence.

An adenoviral vector expressing HXB Nef LL164,165AA was generated by PCR mutagenesis of the HIV molecular clone, HXB-PI (Chen et al., 1996), using the following primers: mutant forward primer, 5′-AATTCCTCAGAATCTCCTCAGACGCCGAG-3′; with reverse primer (3′-hxb-xba), 5′-GCCCTAGGATCCGAGATTTTCAACCCAGCATCTGAAAA-3′; with reverse primer (3′-hxb-xba), 5′-GCCCTAGGATCCGAGATTTTCAACCCAGCATCTGAAAA-3′; and mutant reverse primer, 5′-GCCCTAGGATCCGAGATTTTCAACCCAGCATCTGAAAA-3′. The resulting PCR products were digested and cloned into HIV constructs pseudotyped with VSV-G, as described previously. This vector was then digested with XbaI and BamHI and cloned into the same sites of HXB-PI. The mutated Nef was then amplified and cloned into an adenoviral vector shuttle plasmid as described previously (Swann et al., 2001). The adenoviral vector expressing Nef V10E E317-26 has been described previously (Williams et al., 2004). An HIV molecular clone containing the Nef LL164,165AA mutation was generated by PCR mutagenesis of the HIV molecular clone, HXB-EP (Chen et al., 1996), using the following primers: mutant forward primer, 5′-GAAGGAGAACAAACGGCGCCACCATCGGCTGAGGTTGTC-3′; with reverse primer (3′-hxb-xba), 5′-GCCCTAGGATCCGAGATTTTCAACCCAGCATCTGAAAA-3′; and mutant reverse primer, 5′-GCCCTAGGATCCGAGATTTTCAACCCAGCATCTGAAAA-3′. The resulting mutant PCR products were mixed and reamplified with 3′-hxb-xba and 5′ nef primers, digested with XbaI and BamHI and cloned into the same sites of HXB-EP. The A2/Nef fusion constructs were generated as follows: a PCR prod-
Cells were pulsed with labeling media [prelabel media (Invitrogen). Cells were incubated in prelabel media [RPMI –Cys –Met (Spe-I) and EcoRI. These fragments were then cloned into the BglII and EcoRI sites of a bi-cistronic retroviral vector expressing an IRES GFP cassette containing the HLA-A2 sequence was generated with the primers; HLA-A2/Nef target. The following duplex siRNAs (Ambion) were used in this study: siGFP, sense 5′-GGUCUCUCGGUGAUUCACTT-3′, antisense 5′-GAUGACCUUACGUGCTT-3′; siμ3, sense 5′-GGGACUGUUGGUGAGATT-3′, antisense 5′-CACUCCAAAAUGUGACGTG-3′. The μ1A siRNA was described previously (Hirst et al., 2003). Astrocytoma cells stably expressing CD3 (3′-CD4) were transfected with annealed duplex siRNAs using Lipofectamine 2000 (Invitrogen) following the manufacturer’s protocol. In brief, cells were plated onto 6-well plates (106 cells per well) and the next day each well was transfected with 0.16 nmol siRNA and 4 μl of Lipofectamine 2000 reagent. 24 h later, cells were replated onto 6-well plates (105 cells per well) and the cells were transfected with siRNA again 24 h after replating. 4–6 h after transfection, the media was removed and the cells were transduced with adenovirus (MOI = 50). Cells were harvested and analyzed 24 h after transduction.

For experiments using CEM T cells, the cells were first transduced with adenovirus (MOI = 50). 24 h later, 5 × 106 cells were electrooporated with 1 nmol siRNA according to the manufacturer’s protocol (Anaxa Biosystems). The cells were then incubated for 48 h before FACs and Western blot assays. For Fig. 2 E, the cells were subjected to an initial siRNA transfection 1 d before the adenoviral transduction, and the experiment was then performed as described above.

Antibodies and Western blot analysis

IP-Western experiments were performed as described previously (Williams et al., 2003). HA-HLA-A2 was detected using the anti-HA antibody, HA-11 (1:5,000, Covance). Coprecipitating Nef protein was detected by Western blotting using antibodies obtained via the NIH AIDS Research and Reference Reagent Repository, Division of AIDS, NIAID, NIH: polyclonal anti-Nef antibody [2949, 1:5,000, a gift from R. Swanstrom, The University of North Carolina at Chapel Hill, Chapel Hill, NC, Shugars et al., 1993] or monoclonal anti-Nef (AG11, 1:500 for IP-Westerns and Western blot assays). For Fig. 2 E, the cells were subjected to an initial siRNA transfection 1 d before the adenoviral transduction, and the experiment was then performed as described above.

Online supplemental material

Fig. S1 shows that the addition of an HA tag does not affect MHC-I folding, maturation through the secretory pathway and response to Nef. Fig. S2 demonstrates that Nef targets mature MHC-I for degradation in HIV-infected T cells. Fig. S3 is coimmunoprecipitation and Western blot analyses demonstrating that the dileucine motif is not required for the Nef-MHC-I to recruit AP-1 in HIV-infected T cells. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.200407031/DC1.

We are grateful to Dr. Linton Traub for antibody to μ1A, to the NIH AIDS Research and Reference Repository for antibodies, to Dr. Randy Schekman for helpful suggestions and to Drs. John Moran and Mark Benson for critical reading of the manuscript.

The research was supported by National Institutes of Health grant ROI AI66998. M.R. Kasper was supported by the University of Michigan Genetics Training Program. M. Williams and J. Roeth were supported by the University of Michigan Institute for Clinical and Health Research.
