Centrosomes act as sites of microtubule growth, but little is known about how the number and stability of microtubules emanating from a centrosome are controlled during the cell cycle. We studied the role of the TACC3–XMAP215 complex in this process by using purified proteins and Xenopus laevis egg extracts. We show that TACC3 forms a one-to-one complex with and enhances the microtubule-stabilizing activity of XMAP215 in vitro. TACC3 enhances the number of microtubules emanating from mitotic centrosomes, and its targeting to centrosomes is regulated by Aurora A–dependent phosphorylation. We propose that Aurora A regulation of TACC3 activity defines a centrosome-specific mechanism for regulation of microtubule polymerization in mitosis.

Introduction

In animal cells, microtubules are nucleated from centrosomes and grow out with their plus ends that lead into the cytoplasm (for review see Howard and Hyman, 2003). The number and stability of microtubule plus ends growing from centrosomes changes through the cell cycle, which is concomitant with assembly of the mitotic spindle (Hannak et al., 2001; Kline-Smith and Walczak, 2004; Pielh et al., 2004). One obvious mechanism controlling microtubule assembly at centrosomes is modulation of the microtubule nucleation rate (for review see Job et al., 2003). Indeed, the amount of γ-tubulin increases at centrosomes as cells enter mitosis (Khodjakov and Rieder, 1999; Hannak et al., 2002). However, another equally plausible mechanism is modulation of the stability of nucleated plus ends. The stability of microtubule plus ends is dependent on the rate at which microtubules interconvert between growing and shrinking (called the catastrophe rate) and between shrinking and growing (called the rescue rate; Walker et al., 1988; Howard and Hyman, 2003).

Xenopus laevis egg extracts have been particularly useful for studying the regulation of microtubule polymerization from centrosomes. Because meiotic spindles in Xenopus egg extracts can form without centrosomes by nucleation and stabilization of microtubules around chromosomes (Heald et al., 1996; Karsenti and Vernos, 2001; Sampath et al., 2004), it is possible to study separately the regulation of microtubule polymerization around mitotic centrosomes or chromosomes. In Xenopus egg extracts, the dynamic behavior of microtubules in the cytoplasm is regulated, in large part, by the activity of XMAP215, which is a member of a conserved family of microtubule-associated proteins (Kinoshita et al., 2002; Gard et al., 2004). XMAP215 both stimulates the growth rate and opposes catastrophe activity of XKCM1/XlMCAK, which is member of the Kin I/kinesin-13 family (Walczak et al., 1996; Tournebize et al., 2000; Noetzel et al., 2005). Physiological microtubule dynamics can be reconstituted in vitro by a mixture of XMAP215 and mitotic centromere-associated kinesin (MCAK) together with tubulin (Kinoshita et al., 2001). Although XMAP215 and MCAK clearly have a central role in determining microtubule dynamics in Xenopus egg extracts, we know little about how these proteins are regulated during cell cycle progression. However, these proteins are localized to centrosomes, suggesting that they could be involved in the regulation of microtubule growth from centrosomes (Kinoshita et al., 2002; Gard et al., 2004).

A clue as to the possible mechanisms regulating XMAP215 family proteins at centrosomes came from the
discovery that the Drosophila melanogaster member of the XMAP215 family is associated with D-TACC (D. melanogaster transforming acidic coiled coil; Cullen and Ohkura, 2001; Lee et al., 2001). Mutants in TACC family members reduce microtubule number and prevent the localization of XMAP215 family proteins to centrosomes or spindles in D. melanogaster (Cullen and Ohkura, 2001; Lee et al., 2001), Caenorhabditis elegans (Bellanger and Gönczy, 2003; Le Bot et al., 2003; Srayko et al., 2003), yeasts (Usui et al., 2003; Sato et al., 2004), and human cells (Gergely et al., 2003). Beyond the fact that TACC family members are required to localize XMAP215 family members to centrosomes, we know little about the role of TACC in the modulation of microtubule dynamics and in regulating the activity of XMAP215. In this study, we investigated these issues by using purified proteins and Xenopus egg extracts. Maskin is a Xenopus TACC homologue (Stebbins-Boaz et al., 1999); in this paper, we call it Xenopus TACC3 because of its sequence similarity to the mammalian TACC3 subfamily (Still et al., 2004). We demonstrate that a Xenopus TACC3 is a cell cycle–dependent regulator of XMAP215.

Results

TACC3 forms a complex with and stimulates the activity of XMAP215

To look at the role of the TACC3–XMAP215 complex in microtubule assembly, we studied the activity of the complex in vitro. We first confirmed via immunoprecipitation that native TACC3 and XMAP215 form a protein complex in Xenopus egg extracts (Fig. 1 A). When coexpressed in baculovirus-infected insect cells, recombinant TACC3 and XMAP215 pro-
teins also form a complex (Fig. 1 B). By mixing purified recombinant proteins and performing sucrose gradient centrifugation as well as gel filtration, we showed that TACC3 and XMAP215 form a one-to-one complex with a native molecular mass of \( \sim 366 \text{ kD} \) (Fig. 1, C and D).

Using a mixture of these purified proteins, we monitored the ability of the TACC3–XMAP215 complex to oppose the microtubule-destabilizing activity of MCAK by using a microtubule sedimentation assay (Desai et al., 1999a). In the presence of MCAK, microtubules were completely destabilized (Fig. 2 A, lanes 1 and 2) as reported previously (Desai et al., 1999a). The addition of 500 nM XMAP215 resulted in a slight reduction of MCAK's microtubule-destabilizing activity (Fig. 2 A, lanes 3 and 4). However, XMAP215 that complexed with TACC3 more efficiently opposed the destabilizing activity of MCAK (Fig. 2 A, lanes 5 and 6). TACC3 alone had no detectable effect on MCAK activity (not depicted). One possibility is that TACC3 increases the microtubule-stabilizing activity of XMAP215 by enhancing the affinity of XMAP215 for microtubules. Indeed, microtubule sedimentation analyses that were performed in the absence of MCAK indicated that the TACC3–XMAP215 complex has a higher affinity for microtubules than XMAP215 alone (Fig. 2 B). We have previously shown that XMAP215 opposes MCAK in a dose-dependent manner (Kinoshita et al., 2001). Therefore, we conclude that TACC3 stabilizes microtubules in vitro by forming a complex with XMAP215, increasing the affinity of XMAP215 for microtubules, and, thus, enhancing the antagonizing activity against MCAK.

**TACC3 is required for mitotic microtubule assembly around centrosomes by opposing the activity of MCAK**

To confirm that TACC3 regulates microtubule growth under physiological conditions, we analyzed meiotic spindle assembly in cycling extracts (cycled spindles; Murray, 1991; Desai et al., 1999b). Specifically, we used antibodies to immunodeplete TACC3 from *Xenopus* egg extracts and examined spindle assembly in the depleted extracts. To our surprise, meiotic spindles that assembled in the absence of TACC3 were indistinguishable from spindles that assembled in mock-depleted extracts (Fig. S1, available at http://jcb.org/cgi/content/full/jcb.200503023/DC1) despite the depletion of TACC3 to undetectable levels. Under similar depletion conditions for XMAP215, no spindles were observed. This was unexpected because TACC mutants have phenotypes in mitotic systems that were previously studied (see Introduction; Raff, 2002).

In all systems in which localization has been examined, TACC and XMAP215 are found at centrosomes, suggesting that TACC3 could have a centrosome-specific role in mitosis. Accordingly, we looked specifically at the role of TACC3 in

---

**Figure 3.** TACC3 is required for mitosis-specific microtubule assembly around centrosomes. (A) Microtubules were visualized by the addition of fluorescently labeled tubulin in control mock-depleted (left) and TACC3-depleted extracts (right). Centrosomes were added to interphase extracts (top), and then the extracts were driven into M phase by the addition of nondegradable cyclin B (bottom). Bar, 10 \( \mu \text{m} \). (B) Quantification of tubulin fluorescence in A. (C) Immunoblots of depleted extracts. The extracts were immunodepleted with control IgG (lanes 1 and 2; mock dep) or anti-TACC3 antibody (lanes 3–6; Δ TACC3) with adding back of TACC3 (lanes 5 and 6) or control buffer (lanes 1–4). The blots of interphase (lanes 1, 3, and 5) and mitotic extracts (lanes 2, 4, and 6) were probed by anti-TACC3 (top; TACC3) and anti-XMAP215 (bottom; XMAP215). (D) Microtubules assembled around centrosomes in immunodepleted extracts with add back of recombinant proteins. Purified recombinant TACC3 or control buffer were added in mock-depleted or TACC3-depleted extracts. Bar, 10 \( \mu \text{m} \). (E) Quantification of tubulin fluorescence in D. (F) Inhibition of MCAK in TACC3-depleted extracts. Microtubules were assembled around centrosomes in mock-depleted extracts plus control buffer (left), TACC3-depleted extracts plus control buffer (middle), or anti-MCAK antibody (right). The addition of inhibitory MCAK antibody rescued the effect of TACC3 depletion on microtubule assembly around mitotic centrosomes. Bar, 10 \( \mu \text{m} \). (G) Quantification of tubulin fluorescence in F. (B, E, and G) Relative fluorescence intensity of labeled tubulin around mitotic centrosomes (within 21.079 \( \mu \text{m} \) radius) was measured. Values shown are the means plus SD.
microtubule growth from mitotic centrosomes. Traditionally, centrosomal microtubule assembly has been examined in *Xenopus* egg extracts by adding human centrosomes directly to mitotic extracts (Belmont et al., 1990). However, the formation of a mitotic centrosome is likely to be a complex process involving cell cycle transition. To create mitotic centrosomes, we added isolated centrosomes to interphase extracts and drove the extracts into mitotic (M) phase by the addition of a nondegradable cyclin B (cyclin B Δ90; Glotzer et al., 1991). In mock-depleted extracts, microtubule assembly around centrosomes was activated by the induction of M phase (Fig. 3 A, left). In TACC3-depleted extracts, the microtubule number around centrosomes was decreased to 13% of that in control extracts (Fig. 3 A, right; and B). Importantly, adding back recombinant TACC3 protein to depleted extracts increased microtubule assembly from mitotic centrosomes, returning it to the levels that were found in control extracts (Fig. 3, C–E). In contrast to M phase–induced extracts, no detectable effect of TACC3 depletion was observed on microtubule assembly in interphase extracts (Fig. 3 A, top). We confirmed that TACC3 was localized to these mitotic centrosomes in mock-depleted and TACC3 add-back extracts but not in TACC3-depleted extracts (Fig. 3 D, insets). We conclude that TACC3 is required specifically for microtubule assembly around mitotic centrosomes in *Xenopus* egg extracts.

The in vitro characterization of TACC3 activity suggested the possibility that in the absence of TACC3, microtubules cannot grow from mitotic centrosomes because of high MCAK activity. To test this idea, we examined the effect of MCAK inhibition on microtubule growth in TACC3-depleted extracts. We found that the addition of inhibitory MCAK antibodies to TACC3-depleted extracts stimulated the growth of microtubules from mitotic centrosomes (Fig. 3, F and G). This led to the conclusion that the likely function of TACC3 is to antagonize the microtubule destabilization by MCAK, presumably by increasing XMAP215 activity on centrosomes in M phase but not in interphase.

### Aurora A–phosphorylated TACC3 is enriched at mitotic centrosomes

The results argue that TACC3 activity at centrosomes is specifically required for M phase microtubule growth and poses the question as to whether cell cycle–specific modulation of TACC3 activity could regulate the growth of microtubules from centrosomes. Experiments in *D. melanogaster* and *C. elegans* suggested a role of the mitotic kinase Aurora A in TACC3 localization to centrosomes (Giet et al., 2002; Bellanger and Gönczy, 2003; Le Bot et al., 2003) but could not distinguish between a specific role of the kinase in modulating TACC3 activity at centrosomes and a more general role in regulating centrosome assembly and maturation. Therefore, we decided to investigate the specific role of Aurora A in the regulation of TACC3 localization and activity. TACC3 has three consensus Aurora A sites (Cheeseman et al., 2002) that are conserved between *Xenopus* (Ser33, Ser620, and Ser626) and humans (Ser34, Ser552, and Ser558; Fig. 4 A). Recent experiments have shown that TACC3 is an in vitro substrate of Aurora A in *Xenopus* (at Ser626; Pascreau et al., 2005) and humans (Tien et al., 2004). We confirmed by mass spectrometry that *Xenopus* TACC3 is indeed phosphorylated by Aurora A at these three consensus sites (Fig. S2, available at http://jcb.rupress.org/cgi/content/full/jcb.200503023/DC1). Furthermore, we mutated these three conserved sites to alanine and showed that the incorporation of labeled 32P into the alanine-mutated protein (3A mutant; TACC3-3A) is reduced to 3% compared with the wild-type (WT) protein (TACC3-WT; Fig. 4 B). We raised phosphospecific antibodies to the three conserved Aurora A sites (Fig. 4 C). Because of the limitations of cytology in *Xenopus* systems and in order to use RNA interference as a control for antibody specificity, we examined the localization of phosphorylated TACC3 in human tissue culture cells. Interestingly, phospho-TACC3, which was stained by antibodies against P-Ser626 (in *Xenopus*; Ser558 in humans), localized specifically to mitotic centrosomes, whereas the general population of TACC3, which was stained by polyclonal antibodies against the fragment of TACC3 protein (73–265 amino acids), localized throughout the mitotic spindle as previously reported (Fig. 5 A; Gergely et al., 2000, 2003). siRNA of TACC3 greatly reduced...
the staining of phospho-TACC3 as well as that of nonspecific TACC3 (Fig. 5 B). Phospho-TACC3 antibodies recognized a band of ~130 kD molecular mass specifically in mitosis-arrested tissue culture cells (Fig. 5 C) as well as a band of the same molecular mass that disappeared after the immunodepletion of either TACC3 (see Fig. 6 D) or Aurora A (Fig. S3, available at http://jcb.org/cgi/content/full/jcb.200503023/DC1) from Xenopus egg extracts in mitosis. Therefore, we conclude that TACC3 protein on centrosomes is specifically phosphorylated during M phase by Aurora A.

Phosphorylation of TACC3 by Aurora A is required for its targeting to mitotic centrosomes

To test whether phosphorylation is required to target TACC3 to centrosomes, we examined the localization of the nonphosphorylatable mutant of TACC3 in Xenopus egg extracts. By adding back WT (TACC3-WT) versus alanine-mutated TACC3 (TACC3-3A) to the depleted extracts (Fig. 6 D), we found that centrosomes contained 10% of TACC3-3A compared with TACC3-WT (Fig. 6 A, insets; and B). We confirmed that the TACC3-3A mutant could still interact with XMAP215 both in vitro and in Xenopus egg extracts (Fig. S4, available at http://jcb.org/cgi/content/full/jcb.200503023/DC1). Furthermore, TACC3-3A still enhanced the affinity of XMAP215 for microtubules (Fig. 6 E). Importantly, TACC3-3A cannot target XMAP215 to mitotic centrosomes as efficiently as TACC3-WT (Fig. S5, available at http://jcb.org/cgi/content/full/jcb.200503023/DC1), and this argues that TACC3 phosphorylation by Aurora A is required for efficient centrosomal localization of the TACC3–XMAP215 complex in M phase.

To test whether targeting of TACC3 to centrosomes is required for its activity, we assayed centrosome-mediated microtubule assembly in TACC3-depleted extracts that were reconstituted with either WT or alanine-mutated TACC3. Compared with the WT protein, the alanine-mutated TACC3 could only poorly rescue the effect of TACC3 depletion (Fig. 6, A and C). We confirmed that, after addition to the extract, TACC3-WT was phosphorylated, whereas TACC3-3A was not (Fig. 6 D). Thus, the targeting of TACC3 to centrosomes by Aurora A phosphorylation is required to stimulate microtubule growth from mitotic centrosomes. We were unable to detect any effect of Aurora A phosphorylation of TACC3-WT on its ability to enhance the affinity of XMAP215 for microtubules (Fig. 6 E). This implies that the likely function of Aurora A phosphorylation of TACC3 is targeting of the TACC3–XMAP215 complex to mitotic centrosomes rather than directly regulating its activity toward microtubules.

Discussion

Activation of microtubule assembly by the TACC3–XMAP215 complex on mitotic centrosomes

Previous studies have shown that the combination of XMAP215 and XKCM1/MCAK is essential to promote the dynamic properties of mitotic microtubule assembly (Kinoshita et al. 2005). A nonphosphorylated and nonmitotic TACC3 mutant, TACC3-3A, cannot target XMAP215 to mitotic centrosomes as efficiently as the WT TACC3, indicating the importance of Aurora A phosphorylation for targeting.

To test whether Aurora A is required for the localization of TACC3 to centrosomes, we examined the localization of TACC3 in TACC3-depleted extracts reconstituted with either WT or alanine-mutated TACC3. Compared with the WT protein, the alanine-mutated TACC3 could only poorly rescue the effect of TACC3 depletion. This suggests that the targeting of TACC3 to centrosomes by Aurora A phosphorylation is required to stimulate microtubule growth from mitotic centrosomes. We were unable to detect any effect of Aurora A phosphorylation of TACC3-WT on its ability to enhance the affinity of XMAP215 for microtubules. This implies that the likely function of Aurora A phosphorylation of TACC3 is targeting of the TACC3–XMAP215 complex to mitotic centrosomes rather than directly regulating its activity toward microtubules.

Figure 5. Aurora A phosphorylated TACC3 is enriched at mitotic centrosomes. (A) Immunolocalization of TACC3 and phospho-TACC3. Deconvolved images of human tissue culture cells stained for DNA (blue)/microtubules (MTs; green), TACC3, and phospho-TACC3 (P-TACC3; stained by antiphospho-Ser626 antibodies) in different cell cycle stages. Bars, 10 μm. (B) Immunolocalization of TACC3 and phospho-TACC3 in siRNA-treated cells. Deconvolved images of either control or TACC3 RNA interference–treated cells stained for DNA (blue)/microtubules (MTs; green), TACC3 (top), and phospho-TACC3 (P-TACC3; bottom). Arrows indicate misaligned chromosomes that are indicative of the TACC3 RNA interference phenotype. Bar, 10 μm. (C) Phosphorylation of TACC3 is mitosis specific in human tissue culture cells. The TACC3 antibody detects a protein of ~130 kD in extracts prepared from either an asynchronous culture of HeLa S3 cells (lane 1; I) or cells arrested in mitosis by nocodazole treatment (lane 2; M). The phosphospecific TACC3 antibody (antiphospho-Ser626) recognizes a band with the same molecular mass size in mitotic cells (lane 4) but not in asynchronously cultured cells (lane 3). The blot probed by α-tubulin antibody is a loading control (lane 5, asynchronous cultured cells; lane 6, mitotic arrested cells).
Phosphorylation of TACC3 by Aurora A is required for centrosomal localization of TACC3 and its microtubule-stimulating activity. [A] Localization of WT versus phosphorylation mutant of TACC3 on mitotic centrosomes. Microtubules around mitotic centrosomes were visualized by the addition of fluorescent tubulin in add-back experiments. Bar, 10 μm. Insets show immunolocalization of TACC3 on centrosomes in immunodepleted extracts with add back of WT versus the phosphorylation mutant of TACC3. Bar, 1 μm. [B] Quantification of immunostaining of TACC3 on centrosomes in A. Relative fluorescence intensity of TACC3 staining on centrosomes within 1.079 μm radius was measured. [C] Quantification of tubulin fluorescence in A. Relative fluorescence intensity of labeled tubulin around mitotic centrosomes (within 21.079 μm radius) was measured. [D] Immunoblots of depleted extracts in add-back experiments. Mitotic extracts were immunodepleted with control IgG (lane 1; mock dep) or anti-TACC antibody (lanes 2–4; Δ TACC3) with adding back of control buffer (lanes 1 and 2; + buffer), TACC3-WT (lane 3; + TACC3-WT), or phosphorylation mutant TACC3 (lanes 4; + TACC3-3A). [E] Sedimentation assay to monitor XMAP215 affinity to microtubules in the presence of WT or phosphorylation mutant TACC3. 2.5 μM GMPPCP microtubules were mixed with 0.5 μM XMAP215 alone (lanes 1, 2, 7, and 8), or 0.5 μM XMAP215 + 1.0 μM TACC3-WT (lanes 3, 4, 9, and 10), or 0.5 μM XMAP215 + 1.0 μM TACC3-3A (lanes 5, 6, 11, and 12) in the absence (lanes 1–6) or presence (lanes 7–12) of Aurora A. Mixtures were incubated for 38 min at 30°C and sedimented, and supernatants (S) and pellets (P) were subjected to SDS-PAGE. The gels were stained with Coomassie brilliant blue (top; M XMAP215 alone (lanes 1, 2, 7, and 8)), TACC3-WT (lane 3; + TACC3-WT), or phosphorylation mutant TACC3 (lanes 4; + TACC3-3A). Bar, 10 μm. Insets show immunolocalization of TACC3 on centrosomes in immunodepleted extracts with add back of control buffer (lanes 1 and 2; + buffer), TACC3-WT (lane 3; + TACC3-WT), or phosphorylation mutant TACC3 (lanes 4; + TACC3-3A). Bar, 10 μm.

Microtubule growth from centrosomes or chromosomes requires the presence of XMAP215 (Tournebize et al., 2000). Because Xenopus meiotic spindle assembly is apparently unaffected in the absence of TACC3, it appears that TACC3 is not required for the global activity of XMAP215. Why is TACC3 required specifically for XMAP215 activity at mitotic centrosomes? Our data suggest that targeting of the TACC3–XMAP215 complex to mitotic centrosomes overcomes the high microtubule-stabilizing activity of MCAK at centrosomes. Consistent with this idea, MCAK is localized to centrosomes in many systems (Walczak et al., 1996; Oegema et al., 2001), and colonic and hepatic tumor overexpressed gene (TOG)/TOG protein, which is a human XMAP215 orthologue, is required to protect spindle microtubules from MCAK activity at centrosomes (Holmfeldt et al., 2004). We propose that in the absence of TACC3, XMAP215 is still able to counteract the activity of cytoplasmic MCAK. MCAK localization to centrosomes, however, generates an environment in which plus end growth is not favored, and MCAK cannot stabilize nascent nucleated plus ends. This could either be because MCAK activity at centrosomes is enhanced or because of an increased concentration of MCAK at centrosomes. Targeting of TACC3–XMAP215 would enhance the activity of XMAP215 at centrosomes, stabilizing nascent plus ends and allowing them to grow from centrosomes (Fig. 7). This provides an explanation for the seemingly paradoxical observation that a plus end stabilizer localizes to centrosomes where microtubules are attached via their minus ends (Gard et al., 2004; Gräf et al., 2004).

The centrosome-specific role of TACC3 could explain why the phenotype of RNA interference of TACC family members in tissue culture cells is not very severe. The chromatin-mediated pathway of spindle assembly obscures centrosome-specific effects on microtubule growth. Interestingly, in C. elegans embryos in which mitotic spindle assembly is dominated by its centrosomes, the removal of TACC results in severe microtubule-based phenotypes (Bellanger and Gönçzy, 2003; Le Bot et al., 2003; Srayko et al., 2003).

Aurora A regulates centrosomal microtubule assembly in mitosis

The targeting of TACC3 to centrosomes defines a potential mechanism for regulating the polymerization of microtubules from centrosomes in mitosis. Previous data in other systems has shown that Aurora A is required to target TACC to centrosomes (Giet et al., 2002; Bellanger and Gönçzy, 2003; Le Bot et al., 2003). However, the specific role of TACC3 phosphorylation has been unclear, as Aurora A has general roles in both centrosome assembly and cell cycle progression (Hannak et al., 2001; Giet et al., 2002; Hirota et al., 2003). Our data show that targeting of TACC3 to centrosomes specifically requires...
Aurora A phosphorylation. Furthermore, targeting is essential for TACC activity at centrosomes. Because Aurora A activity increases as cells enter M phase, this would account for the increase in microtubule polymerization that was observed as centrosomes mature during the cell cycle. Consistent with this idea, the protein level of both TACC3 and Aurora A as well as the kinase activity of Aurora A are all highly cell cycle regulated, reaching a peak during mitosis in human tissue culture cells (Bischoff et al., 1998; Gergely et al., 2003). In Xenopus egg extracts, the increase of Aurora A kinase activity may be sufficient to trigger the activation of centrosomal microtubule polymerization in mitosis. Thus, the phosphorylation of TACC3 provides a mechanism for Aurora A to specifically modulate the growth of microtubules from centrosomes. However, Aurora A regulates processes other than microtubule assembly at centrosomes. Identification of the other Aurora A substrates will be essential for understanding the mechanisms of mitotic spindle assembly.

Materials and methods

Expression and purification of recombinant proteins

Full-length Aurora A cDNA was subcloned into pET21 vector (CLONTECH Laboratories, Inc.) for Xenopus Aurora A expression in bacteria (pET21 Aurora A; a gift from J. Swedlow, University of Dundee, Dundee, UK). TACC3 was expressed both in bacteria and insect cells. Full-length TACC3 cDNA was subcloned into pET30 vector (CLONTECH laboratories, Inc.) for expression in bacteria (pET30a maskin; a gift from J. Richter, University of Massachusetts, Worcester, MA). The mutations with an alanine substitution of Aurora A target sites were introduced by PCR. Bacterially expressed Histagged proteins were purified by using Ni-NTA-agarose (Qiagen). For the expression of TACC3 in insect cells, we used the Bac-to-bac baculovirus expression system (Invitrogen). Full-length TACC3 cDNA was subcloned into pFastbac vector for the preparation of bacmid DNA (NhIi terminal His6 tagged). TACC3 baculovirus-infected Sf9 cells (Protein Sciences) were pelleted after a 38 min at 30°C through a glycerol cushion. Equivalent amounts of TACC3 or control buffer were added to reactions. Reactions were quantified, and peak fractions were assigned. Standard curves of peak fractions versus sedimentation coefficient were used to estimate the 5 value of proteins. Standard proteins that were used in sucrose gradients are listed as follows (Stokes radii are indicated in parentheses): ribonuclease A (1.64 nm); chymotrypsinogen (2.6 S); ovalbumin (3.5 S); BSA (4.6 S); aldobase (7.3 S); and catalase (11.3 S).

Figure 7. A model of centrosomal microtubule assembly in M phase. XKCM1/MCAK (red) localized on centrosomes generates an environment in which plus end growth of microtubules (green) is not favored, and XMAP215/TOG (light blue) cannot stabilize nascent nucleated plus ends (left). Aurora A phosphorylation of TACC3/maskin targets the TACC3-XMAP215 complex (dark blue) to centrosomes. The targeting enhances the activity of XMAP215 at centrosomes, stabilizing nascent plus ends and allowing microtubules to grow from centrosomes (right). The encircled P (yellow) represents the serine residues that were phosphorylated by Aurora A in TACC3.

Immunoprecipitation, sucrose density gradient centrifugation, and gel filtration

For immunoprecipitation using insect cell lysates, protein A–Sepharose beads that bound control rabbit lgG or anti-TACC3 antibodies were incubated with lysate from insect cells that were infected either with TACC3 baculovirus or with both TACC3 and XMAP215 baculovirus. Eluted immunoprecipitates were separated by SDS-PAGE and stained by Coomassie brilliant blue.

Sucrose gradients (3–15%) were poured as step gradients (five steps of equal volume) in 1× PBS, 0.1% Tween 20, 1 mM DTT, and 0.2 μg/ml protease inhibitor mix. Gradients were incubated at 4°C for 1 h to allow diffusion into a continuous gradient. Equal concentrations of TACC3 and XMAP215 were mixed in vitro, incubated for 10 min on ice, diluted into gradient buffer to a final concentration of 1% glycerol, loaded onto the gradient, and spun for 6.5 h at 4°C and 120,000 g. Gradients were fractionated from the top by hand with a cut pipette tip. Fractions were analyzed by 4–12% SDS-PAGE (NuPage; Invitrogen) and stained by Coomassie brilliant blue. Standard proteins with known sedimentation values were run in parallel and scanned. Band intensities were quantified, and peak fractions were assigned. Standard curves of peak fractions versus sedimentation coefficient were used to estimate the 5 value of proteins. Standard proteins that were used in sucrose gradients are listed as follows (Stokes radii are indicated in parentheses): ribonuclease A (1.64 nm); chymotrypsinogen (2.09 nm); ovalbumin (3.05 nm); BSA (3.55 nm); aldobase (4.81 nm); catalase (5.22 nm); ferritin (6.1 nm); and thyroglobulin (8.5 nm).

Depolymerization assay and sedimentation analysis of stabilized microtubules

Sedimentation analysis of the depolymerization of GMPCPP-stabilized microtubules was performed as described previously (Desai et al., 1999a). 2.5 μM of depolymerized GMPCPP microtubules were added to the reaction mix that was supplemented with 125 nM MCAK or control buffer in 1× BRB80 (80 mM Pipes, pH 6.8, 1 mM MgCl2, and 1 mM EGTA) containing 125 mM KCl and 1.5 mM MgATP. 500 nM XMAP215 and increasing amounts of TACC3 or control buffer were added to reactions. Reactions were sedimentated after 30 min at 30°C through a glycerol cushion. Equivalent amounts of the supernatant and pellets were analyzed by 4–12% SDS-PAGE followed by Coomassie brilliant blue staining. For sedimentation...
assays to monitor the affinity of XMAP215 to microtubules, 2.5 μm of prepolymerized GMPCPP microtubules were incubated with 500 nM XMAP215 or control buffer in 1× BRB80 containing 125 mM KCl in the presence of TACC3 or control buffer. In each condition, we confirmed that all proteins were in the supernatant after sedimentation without GMPCPP microtubules.

Preparation of Xenopus egg extracts and immunodepletion
Xenopus egg extracts were prepared as described previously (Murray, 1991; Desai et al., 1999b). Interphase extracts were prepared by the addition of calcium to cytoskeletal factor extracts. Cycloheximide was added to 100 μg/ml to avoid translation of cyclin B messenger in extracts and to arrest them in interphase. To generate interphase extracts, a purified, nondegraded cyclin B fragment (cyclin BΔD90; a gift from P. Gönczy, The Rockefeller University, New York, NY; Glotzer et al., 1991) was added to 25 μg/ml to interphase extracts (Vorlauer and Peters, 1998; Funabiki and Murray, 2000). Immunodepletion in Xenopus egg extracts was performed as described previously (Funabiki and Murray, 2000). All of the immunodepletion experiments were performed in the presence of 100 μg/ml cycloheximide in extracts to block translation, as maskin has been reported to be a negative regulator of translational machinery during oocyte maturation (Stebbins-Boaz et al., 1999).

Antibodies and immunoblotting
Phosphospecific antibodies were raised and purified against phosphopeptides including phosphothreonine in the consensus target sites of Aurora A phosphorylation in Xenopus TACC3 (P-Ser33; QTGPGRphospho-SLIRPSQ and P-Ser620; CNFSKPGphospho-SLRKPG and P-Ser626; VRKQphospho-SLYLFC). Anti–Xenopus TACC3 antibodies were purified and phosphorylated against the GST fusion protein that contained an NH₂-terminal fragment of TACC3 (aa 7–208). Anti–human TACC3 antibodies were previously described (Gergely et al., 2000). Anti–Aurora A and XMAP215 antibodies were raised and purified against COOH-terminal peptides (Aurora A, CKNSQIKKDEPLPGAQ; XMAP215, CNNIDKIKRLEKSSRK) as described previously (Field et al., 1998). Anti–tubulin antibodies (DM1A) were purchased from Sigma-Aldrich, Anti–NH₂-terminal fragments of XMAP215 (KKCM1-NI) antibodies were gifts from C. Walczak (Indiana University, Bloomington, IN; Walczak et al., 1996). Immunoblotting was performed by using ECL (GE Healthcare). For quantification of phospho-TACC3 signal, the signal intensities on the blot were measured by image software (Scion Corp.).

Microtubule assembly and localization assays using Xenopus egg extracts Recycled and fluorescently labeled tubulins (rhodamine- or Cy3-labeled) were prepared from porcine instead of bovine brain as previously described (Hyman et al., 1991; Ashford et al., 1998). Centrosomes were purified from human KE37 cells as described previously (Moudjou and Bornens, 1998). Xenopus interphase egg extracts that were supplemented with centrosomes (5 × 10⁶/ml final) and fluorescently labeled tubulin (0.5–1 μM final) to visualize microtubules were incubated with or without cytochalasin B (20 μM) for 30 min at RT. After fixation, the incorporation of 32P into the TACC3 in the gel was detected by autoradiography by using a phosphomager (model BAS-1800II; Fujifilm). Mass spectrometric analysis for identification of in vitro Aurora A phosphorylation sites of TACC3 was performed as described previously (Kraft et al., 2003).

Cell culture and RNA interference
HeLa cells were grown in DME containing 10% serum supplemented with nonessential amino acids (GIBCO BRL) and were grown using standard procedures. For RNA interference, HeLa cells were seeded onto glass coverslips 16 h before transfection. Cells were transfected with a vector containing 10% serum supplemented with nonessential amino acids (Biochrom) by using standard procedures. Cells were arrested in mitosis by the addition of 90 ng/ml nocodazole (Sigma-Aldrich) 20 h before harvesting and were shown to be >95% mitotic as judged by DAPI staining.

Immunofluorescence and microscopy for culture cells
Transfected HeLa cells that were grown on coverslips were fixed and permeabilized in methanol at −20°C for 8 min. Cells were washed with PBS and incubated 10 min in PBS containing 0.2% fish skin gelatin (PBS-FSG; Sigma-Aldrich) to prevent nonspecific binding of antibodies. Cells were incubated 20 min with primary antibody. Antibodies that were used were anti–tubulin (DM1A; Sigma-Aldrich), anti-TACC3 (Gergely et al., 2000), and antiphospho-TACC3 (anti–P-Ser626 in this study) diluted to 1 μg/ml in PBS-FSG. After washing in PBS, cells were incubated for 20 min at 37°C in 1 μg/ml−1 (in PBS-FSG) of donkey secondary antibodies that were labeled with either Texas red, FITC, or Cy5 (Jackson ImmunoResearch Laboratories) and were washed in PBS before mounting in the presence of 1 μg/ml−1 DAPI to visualize chromatin. Three-dimensional datasets were acquired on an imaging system (DeltalView; Applied Precision) that was equipped with a microscope (model IX70; Olympus), a camera (CoolSNAP, Roper Scientific), and a 100× NA 1.4 plan-Apochromat objective. Images were computationally deconvolved by using the SoftWorx software package (Applied Precision) and were shown as two-dimensional projections.

Online supplemental material
Fig. S1 shows spindles assembled in mock-depleted versus TACC3-depleted Xenopus egg extracts. Fig. S2 shows in vitro phosphorylation sites in TACC3/maskin as determined by mass spectrometry. Fig. S3 shows TACC3 phosphorylation in Aurora A-depleted extracts. Fig. S4 shows the phosphorylation of phospho-kinase mutant TACC3 in Xenopus egg extracts and in vitro. Fig. S5 shows centrosomal localization of XMAP215-GFP in Xenopus egg extracts. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.200503023/DC1.

We are grateful to Jason Svedlow and Joan Ruderman (Harvard Medical School, Boston, MA) for cDNA of Aurora A/Eg2, Joel Richter for cDNA of Xenopus TACC3/maskin; Hironori Funabiki for purified cyclin B A90; Claire Walczak for anti-XKCM1/MCAK antibodies; Heino Andreas [MPBCG] for help with the frog colony; Andrej Pozniakowski [MPBCG] for plasmid construction of the alanine-mutated TACC3; and Anshad Desai (University of California, San Diego, San Diego, CA) for pCAGGS-HA. K. Kinoshita was supported by a research fellowship from the Uehara Memorial Foundation and a grant from the Deutsche Forschungsgemeinschaft priority program Molecular Motors. L. Pelletier was supported by a postdoctoral fellowship from the Human Frontier Science Program.
