Tubulin tyrosination is a major factor affecting the recruitment of CAP-Gly proteins at microtubule plus ends

In most eukaryotic cells, the C terminus of α-tubulin is subject to a cycle of detyrosination–tyrosination, in which the C-terminal tyrosine residue of α-tubulin is sequentially cleaved from the peptide chain by tubulin carboxypeptidase (TCP) and readded to the chain by the tubulin-tyrosine ligase (TTL; Barra et al., 1988). In both animal models and human cancers, TTL is often suppressed during tumor growth, indicating that TTL suppression and resulting tubulin detyrosination represent a strong selective advantage for proliferating transformed cells (Lafanechere et al., 1998; Mialhe et al., 2001). In whole animals, TTL is essential for neuronal organization: TTL-null mice die within hours after birth because of the disorganization of vital neuronal circuits (Erck et al., 2005). In Saccharomyces cerevisiae, where the tyrosination cycle does not occur but where the structure of the α-tubulin C terminus is conserved, removal of the C-terminal aromatic residue of α-tubulin (a phenylalanine in yeast instead of a tyrosine) disables the interaction of microtubule (MT) plus ends with Bik1p, the yeast equivalent of the mammalian MT plus-end tracking protein cytoplasmic linker protein (CLIP) 170 (Badin-Larcon et al., 2004). Consistent with a role of tubulin tyrosination in CLIP-170 localization, CLIP-170 is mislocalized in TTL-null neurons, being absent from the distal part of neurites and from growth cones (Erck et al., 2005).

In this study, we have used TTL-null fibroblasts, in which, in contrast with neurons, individual MTs are distinct, to probe the influence of tubulin tyrosination on the recruitment of CLIP-170 and of other MT plus-end proteins (+TIPs) at MT ends.

We find that tubulin tyrosination is important for proper localization of +TIPs such as CLIP-170, CLIP-115, or p150 Glued, which comprise at least one cytoskeleton-associated protein glycine-rich (CAP-Gly) MT binding motif (Carvalho et al., 2003; Akhmanova and Hoogenraad, 2005), whereas other +TIPs, such as EB1, EB3, CLIP-associating protein (CLASP), or mitotic centromere-associated kinesin (MCAK), interact similarly with tyrosinated or detyrosinated polymers. We provide evidence that TTL suppression and resulting tubulin detyrosination induce abnormalities in spindle positioning and in cell morphology.

Results

Tubulin tyrosination in wild-type (WT) and TTL-null fibroblasts

TTL-null cells contain massive amounts of detyrosinated (Glu) tubulin but also variable amounts of tyrosinated (Tyr) tubulin originating from tubulin synthesis (Erck et al., 2005). Here, when double stained for Tyr and Glu tubulin, interphasic WT cells displayed extensive tyrosination of cytoplasmic MTs, with only a small subset of Glu MTs (Fig. 1A), known to correspond to poorly dynamic polymers (Gundersen et al., 1984; Kreis, 1987; Wehland and Weber, 1987). Interphase TTL-null fibroblasts contained extensive arrays of Glu MTs and variable amounts of Tyr tubulin (Fig. 1A). In four independent experiments, 11–15% of TTL-null fibroblasts displayed only background signal when stained with Tyr tubulin antibody (Fig. 1, A–C, Tyr−). 50–60% of the cells showed partial staining of the MT network (Fig. 1, A–C, Tyr+), and 30–40% of the cells showed distinct staining of the whole MT network (Fig. 1, A–C, Tyr++). All Tyr− cells were also negative for the G2/S marker cyclin A, indicating that all were G1 cells (Fig. 1D).

When MT stability was probed using cell exposure to nocodazole (unpublished data), the bulk of cytoplasmic MTs in all WT or TTL-null cells were nocodazole sensitive, indicating that in interphase TTL-null cells, MT detyrosination was not due to increased MT stability.

In WT mitotic cells, Tyr tubulin antibody stained both the central region of the spindle and the cell periphery, which contains a free tubulin pool and astral MTs. The Glu tubulin signal was low, with a distinct staining of centrioles (Fig. 1E). In TTL-null mitotic cells, the Tyr tubulin signal was evident in prophase and remained strong through the whole mitotic process (Fig. 1E).

In metaphase or anaphase cells, spindle MTs were stained with both Tyr and Glu tubulin antibody. Interestingly, in all metaphase cells examined, Tyr tubulin staining was apparently enriched in the core region of the spindle, with no detectable signal at the periphery of the cell, where Glu tubulin staining yielded both a diffuse signal corresponding to the soluble tubulin pool and a distinct staining of astral MTs.

Collectively, these results indicate that tubulin detyrosination is maximal in interphase TTL-null fibroblasts, where G1 cells can lack detectable Tyr tubulin. Tyr tubulin is present in G2/S and throughout mitosis. Additionally, in metaphase TTL-null cells, Tyr tubulin seems to be preferentially recruited to core

Figure 1. Tubulin tyrosination in WT or TTL-null fibroblasts. (A) Double immunostaining of Tyr and Glu tubulin in WT or TTL-null (TTL KO) interphase fibroblasts. MT network of WT fibroblasts was mainly composed of Tyr tubulin. TTL-null fibroblasts contained extensive arrays of Glu MTs and variable amounts of Tyr tubulin. Some cells (Tyr−) showed only background signal. Other cells showed distinct but incomplete staining of the MT network (Tyr+). Finally, a proportion of the cells (Tyr+) showed staining of most of the MT network. (B) Fluorescence intensity of Tyr tubulin signal (arbitrary units) in WT (n = 90), TTL-null Tyr− (n = 90), TTL-null Tyr+ (n = 32), and TTL-null Tyr+ fibroblasts (n = 58). Fluorescence intensity was < 200 au in Tyr− cells and > 400 au in Tyr+ cells. (C) Proportions of Tyr−, Tyr+, and Tyr+ cells in a TTL-null population (n = 308). Error bars indicate SEM. (D) Proportion of cyclin A+ cells (S/G2 cells) in Tyr−, Tyr+−, or Tyr+− interphase TTL-null fibroblasts (n = 125). Note that all the Tyr− cells were also cyclin A−. (E) Double immunostaining of Tyr and Glu tubulin in WT and TTL-null mitotic fibroblasts. Note that in metaphase TTL-null mitotic fibroblasts, Tyr tubulin is only detectable in central spindle MTs, whereas astral MTs and the soluble tubulin pool are composed of Glu tubulin. More than 50 mitotic cells were examined in each genotype. Bars, 10 μm.
spindle MTs, which include the slowly treadmilling k inetochore-to-pole fibers (Mitchison, 1989), whereas the soluble tubulin pool and the dynamic astral MTs are essentially composed of Glu tubulin.

**CLIP-170 localization in WT and TTL-null fibroblasts**

Previous evidence has suggested that CLIP-170 association with growing MT plus ends is inhibited by tubulin detyrosination, whereas EB1 localization is unaffected (Badin-Larcon et al., 2004; Erck et al., 2005). To assess CLIP-170 localization as a function of tubulin tyrosination, WT or TTL-null cells were triple labeled with EB1 antibody, CLIP-170 antibody, and Tyr tubulin antibody (Fig. 2, A and B). In WT cells, CLIP-170 colocalized with EB1 in comet-like structures at MT ends. Similar colocalization was observed in Tyr+ TTL-null cells. In contrast, Tyr− TTL-null cells were essentially devoid of CLIP-170 comets. For quantitative analysis of CLIP-170 localization on growing MT plus ends, 30 EB1-labeled MT ends were selected in each individual cell and examined for CLIP-170 labeling, and the percentage of CLIP-170–positive MT ends (CLIP-170+) was determined. All measurements were performed blind to genotype. In interphase WT cells, >87% of the EB1+ MT ends were also positive for CLIP-170 (Fig. 2 C). In TTL-null cells,
a strong relationship between tubulin tyrosination and CLIP-170 localization was evident, with only 14% of the EB1-labeled MT ends being also positive for CLIP-170 in cells classified as Tyr−, compared with 80% of positive ends in cells classified as Tyr+ (Fig. 2 C). CLIP-170/EB1 fluorescence ratios were higher in WT cells than in Tyr+ TTL-null cells and close to background levels in Tyr− TTL-null cells (Fig. 2 D a). The few CLIP-170 comets visible in Tyr− cells had low CLIP-170 signal compared with CLIP-170+ comets in Tyr+ or WT cells (Fig. 2 D b).

In a series of control experiments, we checked that CLIP-170 expression levels were not different in WT cells compared with TTL-null cells (Fig. 2 E). We also checked by cyclin A staining that a similar proportion of G1 (75%) and G2/S cells were present in WT or TTL-null cell populations and that in WT cells, CLIP-170 localization was not detectably different in cyclin A− cells compared with cyclin A+ cells (unpublished data). CLIP-170 localization at growing MT plus ends could be influenced by MT growth rates. We used video microscopy and fluorescent protein constructs to test whether MT growth rates differed as a function of the tubulin tyrosination status. In cells double transfected with GFP–CLIP-170 and EB3–RFP, GFP–CLIP-170 behaved as endogenous CLIP-170, associating with MT ends in WT cells and in Tyr+ TTL-null cells but not in Tyr− TTL-null cells, indicating that tyrosination affects CLIP-170 localization within a large range of protein expression levels (Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200512058/DC1). We measured MT growth rates in double-transfected cells by video microscopy tracking of EB3–RFP–labeled MT ends. Interestingly, we observed similar MT growth rates in WT cells compared with TTL-null cells, whether or not CLIP-170 was correctly localized (Fig. 2 F and Videos 1–3), indicating that CLIP-170 mislocalization is not due to impaired MT growth in TTL-null cells but likely reflects an influence of tubulin detyrosination by itself.
In WT mitotic cells, many CLIP-170 and EB1 comets were visible (Fig. 3). In TTL-null mitotic cells, which contain abundant Tyr tubulin, CLIP-170 comets were also conspicuous (Fig. 3). However, interestingly, in TTL-null metaphase cells, whereas CLIP-170 staining of the core spindle was similar to that observed in WT cells (and as found in previous work [Tanenbaum et al., 2006]), CLIP-170 comets were undetectable at the cell periphery, compatible with a lack of CLIP-170 interaction with the detyrosinated astral MTs (see Figs. 2 and 3). Comets reappeared at the cell periphery in telophase, presumably when Tyr tubulin from the disassembling core spindle MTs redistributed among astral MTs. Collectively, our results indicate that in TTL-null cells, MT tyrosination is critical for CLIP-170 association with MT ends.

Effect of the inhibition or rescue of tubulin tyrosination on CLIP-170 localization in TTL-null fibroblasts

The evidence we have shown indicates a strong correlation between MT tyrosination and CLIP-170 localization. We used experimental manipulation of the tubulin tyrosination level in TTL-null cells to test the causal nature of this relationship. For Tyr tubulin depletion, we made use of previously described α-tubulin siRNAs, which suppress α-tubulin synthesis and thereby the Tyr tubulin pool in TTL-null cells (Erck et al., 2005). WT controls or TTL-null fibroblasts were transfected with GFP–CLIP-170 and exposed to α-tubulin siRNA. These siRNAs have no effect on tubulin tyrosination in WT cells, where tubulin is tyrosinated by TTL. In these cells, the MT network was somewhat disorganized (Erck et al., 2005; Fig. 4 A), but MT ends remained uniformly positive for GFP–CLIP-170. In contrast, α-tubulin siRNAs induced extensive suppression of Tyr tubulin in TTL-null cells (Fig. 4, A and B). Accordingly, we did not observe CLIP-positive cells among siRNA-treated TTL-null fibroblasts (Fig. 4, A and C). Conversely, cotransfection of TTL-null cells with TTL cDNA together with GFP–CLIP-170 dramatically increased both the level of MT tyrosination and the proportion of cells with CLIP-170 at MT ends (Fig. 4). We observed similar results with endogenous protein as with transfected GFP–CLIP-170 (unpublished data). In control experiments, no change in the proportion of G1 versus G2/S cells was detectable after the various cell treatments. These results strongly indicate that CLIP-170 mislocalization is causally related to tubulin detyrosination in TTL-null cells.

Differential binding of CLIP-170 head domain (HD) to tyrosinated and detyrosinated MTs

Is the influence of tubulin tyrosination on CLIP-170 interaction with MTs direct or indirect? To approach this question, we examined the interaction of the CLIP-170 HD, which contains the...
MT binding domain CAP-Gly (Perez et al., 1999; Scheel et al., 1999), with Tyr or Glu MTs, both in vivo and in vitro. When WT fibroblasts were transfected with CLIP-170 HD fused with YFP (CLIP-170–HD–YFP), CLIP-170–HD–YFP formed comets at MT ends and decorated MTs lengthwise (Fig. 5 A). Interestingly, the comets and the lengthwise MT signal were both lacking in TTL-null Tyr− cells (Fig. 5 A). We then tested whether a differential binding of CLIP-170 HD to Tyr or Glu MTs could be reconstituted in purified systems in vitro. CLIP-170 HD (His–CLIP-170 H1; Scheel et al., 1999) was added in substoichiometric amounts to solutions of affinity-purified Tyr or Glu tubulin (Paturle et al., 1989). Subsequently, tubulin polymerization was initiated and taxol was added to stabilize MTs. At low ionic strength, CLIP-170 HD was quantitatively absorbed on both Tyr and Glu MTs. We then tested the effect of increasing NaCl concentrations. Taxol-stabilized MTs were then exposed to increasing NaCl concentrations before the cosedimentation assay of CLIP-170 with MTs (Bulinski et al., 1999). His–CLIP-170 HD showed a double band with a molecular mass of 40 kD as observed in Scheel et al. (1999). Interestingly, CLIP-170 HD began to be eluted from Glu MTs at 100 mM NaCl (Fig. 5, C [**] and D) and was further dissociated from Glu MTs at 200 mM NaCl (Fig. 5, C [#] and D), whereas at similar NaCl concentrations, the bulk of CLIP-170 HD

Figure 6. MT end composition in WT and TTL-null fibroblasts. (A) Double staining of EB1 and CLIP-115, EB1-GFP and p150 Glued, EB1 and GFP-MCAK, or EB1 and GFP-CLASP in WT or TTL-null (TTL KO) cells. In WT fibroblasts, endogenous CLIP-115 and p150 Glued showed a comet-like distribution at MT ends. In TTL-null fibroblasts, Tyr−, CLIP-115, and p150 Glued did not decorate MT ends and showed a diffuse distribution in the cytoplasm. GFP-MCAK and -CLASP equally decorated MT ends in WT or TTL-null Tyr− cells. More than 50 cells were examined in each genotype for each condition. Bars, 10 μm. (B) Western blot analysis of CLIP-115, p150 Glued, and EB1 content in a WT or TTL-null fibroblast extract. Equal amounts of proteins were loaded in each line. (C, a) MT binding assay of p150 Glued HD. p150 Glued HD was copolymerized with Tyr or Glu tubulin. Tyr and Glu MTs were stabilized with taxol and incubated with increasing concentrations of NaCl, as indicated. Equal amount of supernatants (S) and pellets (P) were loaded onto an SDS-PAGE gel and stained with Coomassie blue. p150 Glued HD showed a band with a molecular mass close to 30 kD. In the presence of 100 mM NaCl, a small proportion of p150 Glued HD eluted from Tyr MTs (**), whereas about half of the p150 Glued HD eluted from Glu-MTs (##). In the presence of 200 mM NaCl, less than a half of p150 Glued HD eluted from Tyr MTs (#), whereas the main proportion of p150 Glued HD eluted from Glu MTs (##). Tyr and Glu MT final concentration was 12 μM, and p150 Glued HD final concentration was 5 μM. (b) Quantitative analysis of p150 Glued HD elution from Tyr or Glu MTs at different NaCl concentrations. Mean value ± SEM of p150 Glued HD present in the supernatant fraction (S/S + P) of Tyr or Glu MTs (n = 7). **, P < 0.01; *, P < 0.05 (t test).
was still associated with Tyr MTs (Fig. 5, C [* and #] and D). Interestingly, the differential binding of CLIP-170 HD to Glu or Tyr MTs occurred at NaCl corresponding to the intracellular NaCl concentration (150 mM). CLIP-170 HD binding to Tyr and Glu MTs was then tested at different tubulin concentrations at 150 mM NaCl. CLIP-170 HD was present in supernatants at all concentrations with Glu MTs, whereas it only appears in supernatants at close to saturating concentrations (5 μM CLIP-170 HD for 6 μM tubulin) with Tyr MTs (Fig. 5 E). At the same NaCl concentration, a His-EB1 construct was still quantitatively absorbed on both Tyr and Glu MTs (Fig. 5 E) and began to be eluted only at 500 mM NaCl, similarly from Tyr or Glu MTs (not depicted). Collectively, these results indicate that tubulin tyrosination interferes directly with CLIP-170 interaction with MTs but does not affect other +TIPs with different MT binding domain, such as EB1.

**Tubulin tyrosination affects MT interaction with CAP-Gly end-tracking proteins**

The CAP-Gly MT binding domain of CLIP-170 is also present in the MT end-tracking proteins CLIP-115 and p150 Glued. The HDs of CLIP-115 and -170 are homologous, and in this study, in all qualitative and quantitative cellular assays, endogenous CLIP-115 or the GFP–CLIP-115 construct behaved like CLIP-170, binding to Tyr but not to Glu MTs (Fig. 6 A and not depicted). Interestingly, endogenous p150 Glued or the EGFP–p150 Glued construct also behaved like CLIP-170 in similar assays (Fig. 6 A and not depicted). In vitro MT binding assays, a differential binding of p150 Glued to Tyr or Glu MTs was always detectable, although less evident than in the case of CLIP-170 (Fig. 6, A and C). We have shown that, in contrast, EB1 and EB3, two highly related proteins whose MT binding domain does not comprise a CAP-Gly motif, are unaffected by MT tyrosination in vivo (Figs. 2–6 and Videos 1–3) and in vitro (Fig. 5 E). MCAK, which has recently been shown to end track MTs (Moore et al., 2005), and CLASPs, a previously identified +TIP (Akhmanova et al., 2001), also decorated MT plus ends in Tyr− TTL-null cells (Fig. 6 A). We conclude that tubulin tyrosination affects MT interactions with CAP-Gly +TIPs in the absence of obvious effects on the behavior of other +TIPs. TTL-null cells then offered an original system in which a single amino acid deletion in α-tubulin, not affecting protein folding, specifically disrupted the interaction of MTs with CAP-Gly +TIPs. The most obvious cellular consequences of such a disruption are shown in the next sections.

**Cell morphology and polarization in TTL-null fibroblasts**

CAP-Gly +TIPs are involved in MT interactions with the cell membrane (Brunner and Nurse, 2000; Akhmanova et al., 2001; Komarova et al., 2002; Carvalho et al., 2003; Busch and Brunner, 2004; Lansbergen et al., 2004; Akhmanova and Hoogenraad, 2005; Mimori-Kiyosue et al., 2005), and there is evidence that tubulin detyrosination affects cell morphogenesis in neurons (Erck et al., 2005). In nonneuronal cells, it has been suggested that the presence of CLIP-170 at MT ends is important for MT-dependent regulations of actin assemblies, such as lamellipodia (Fukata et al., 2002; Gundersen, 2002). Upon examination, WT fibroblasts often displayed a distinct polarity by extending a single lamellipodium (Fig. 7, A), as expected from the behavior of a normal fibroblast, which extend a lamellipodium in the direction of cell migration (Pollard and Borisy, 2003). Similar polarized lamellipodium extension was never observed in Tyr− TTL-null cells, which showed a more or less regular round shape (Fig. 7 A), whereas Tyr+ TTL-null fibroblasts often displayed numerous extensions with several large lamellipodia, resulting in a conspicuously irregular cell shape (Fig. 7 A). We used a standard shape factor (defined by 4πA/P²,

---

**Figure 7. Morphological analysis of WT or TTL-null fibroblasts.** (A) Double staining of actin and Tyr tubulin in WT or TTL-null (TTL KO) fibroblasts. WT cells often showed a polarized morphology with a large lamellipodium. Tyr+ TTL-null fibroblasts often displayed two or more lamellipodia. In contrast, Tyr− TTL-null fibroblasts lacked distinct polarization. Bars, 10 μm. (B) The graph depicts morphology. A shape factor (4π area/perimeter²) was determined in WT or TTL-null fibroblasts. (a) Shape factor distribution in WT (n = 43), TTL-null Tyr+ (n = 36), or TTL-null Tyr− fibroblasts (n = 34). (b) Shape factor mean values ± SEM. Compared with WT or Tyr+ TTL-null fibroblasts, Tyr− TTL-null cells exhibited a significant increase in the shape factor. ***, P < 0.001 (t-test). (C) Quantitative analysis of the percentage of cell perimeter occupied by lamellipodia in WT, Tyr−, or Tyr+ TTL-null cells. (b) Number of lamellipodia per cell in WT, Tyr−, or Tyr+ TTL-null cells. Tyr− TTL-null cells often displayed no lamellipodia extensions. In contrast, Tyr+ TTL-null cells exhibited an increased number of large lamellipodia extensions compared with WT fibroblasts [WT, n = 68; Tyr−, n = 20; Tyr+, n = 38]; ***, P < 0.001; *, P < 0.05 (t-test).
where A is the area and P the perimeter) for quantitative analysis of cell shape. This shape factor varies from 0 to 1, for elongated or circular shapes, respectively. Compared with WT cells, Tyr− TTL-null cells had an increased shape factor, indicative of a more regular, round shape (Fig. 7 B). Among WT cells, shape factors were similar between G1 in G2/S cells (unpublished data). Tyr+ TTL-null cells had a mean shape factor comparable to that of WT cells, although there was an excess population of cells with a low shape factor (Fig. 7 B), indicative of irregular and elongated cell shape.

In a further quantitative analysis, the ratio of the perimeter of large lamellipodia extensions to the total cell perimeter was dramatically diminished in Tyr− TTL-null cells compared with other cells (Fig. 7 C a), and the number of large lamellipodia extensions per cell was increased in Tyr+ TTL-null cells, compared with WT cells (Fig. 7 C b). We conclude that cell morphology is perturbed in TTL-null cells, apparently because of abnormalities in cell polarization, which seems inhibited in Tyr− cells and disorganized in Tyr+ cells.

**Defects in spindle positioning in mitotic TTL-null fibroblasts**

Spindle positioning is dependent on +TIP-mediated interactions of astral MTs with the cell cortex (Busson et al., 1998; Carvalho et al., 2003; Akhmanova and Hoogenraad, 2005; Huisman and Segal, 2005). We used printed micropatterns of fibronectin to study spindle positioning in WT or TTL-null fibroblasts. Micropatterns constrain extracellular matrix organization and thereby organization of both actin assemblies and cell adhesions, which are important for spindle positioning (Thery et al., 2005). We observed similar organization of actin assemblies or cell adhesions in TTL-null cells and WT cells placed on micropatterns (unpublished data). Spindle positioning then depends crucially on astral MT interactions with the metaphase cell cortex (Thery et al., 2005). These interactions involve CAP-Gly +TIPs (Busson et al., 1998), which fail to associate with astral MT ends in TTL-null cells.

The majority of mitotic spindles of WT cells grown on L-shaped patterns were oriented along the hypotenuse (Fig. 8 A, a–c). In contrast, there was a wide dispersion of spindle orientations in TTL-null cells (Fig. 8 A, d–f), with ~70% of spindles deviating by >15° from the median angle compared with only 30% in WT cells (Fig. 8 B), indicating an impaired control of spindle positioning in TTL-null cells.

**Discussion**

In this study, we show that tubulin tyrosination is central for MT interaction with CAP-Gly +TIPs and that in cells, TTL suppression and resulting tubulin detyrosination affect spindle positioning and cell morphology. Tyr tubulin is not fully suppressed in TTL-null cells (Erck et al., 2005), where Tyr tubulin arises from synthesis of new tubulin molecules. Tyr tubulin levels vary in interphase cells that can exhibit complete detyrosination. In contrast, mitotic cells always contain Tyr tubulin. The constant presence of Tyr tubulin in mitotic TTL-null cells compared with interphase TTL-null cells is intriguing. We do not know whether this uniform presence of Tyr tubulin reflects an increased tubulin synthesis when cells enter mitosis, an inhibition of TCP, or both.

Based on Tyr and Glu tubulin distributions in metaphase TTL-null cells, our data raise the possibility of a preferential recruitment of Tyr tubulin compared with Glu tubulin in kinetochore-to-pole MTs, with a corresponding enrichment of Glu tubulin in astral MTs and in the soluble tubulin pool. Such a preferential recruitment cannot be explained by a difference in Tyr or Glu MT polymerization properties (Paturel et al., 1989). However, recent work in *Drosophila melanogaster* indicates that tubulin incorporation in the treading kinetochore-to-pole MTs during metaphase does not depend only on the intrinsic polymerization properties of tubulin but also on specific regulations that, in *D. melanogaster*, require CLASP (Maia et al., 2005). Possibly, tubulin incorporation in kinetochore-to-pole fibers also requires CAP-Gly proteins or other unknown proteins whose interaction with MTs depends on tubulin tyrosination. We do not know whether mitotic cells could tolerate the complete suppression of Tyr tubulin. We have observed extensively detyrosinated mitotic cells in siRNA experiments (unpublished data). In these cells, the spindle was conspicuously disorganized, but we found it hard to know whether spindle anomalies were due to tubulin...
detyrosination by itself or to other dysfunctions related to the inhibition of α-tubulin synthesis.

In TTL-null cells, tubulin detyrosination affects the recruitment of CAP-Gly proteins at MT ends, whereas EB1 localization is unaffected. Additionally, we observe that tubulin tyrosination affects the interaction of MTs with CAP-Gly + TIPs in purified systems in vitro. Clearly, as suggested by previous studies (Perez et al., 1999; Galjart and Perez, 2003; Badin-Larcon et al., 2004), CLIP-170 and p150 Glued localization at MT ends depends crucially on direct interactions between these + TIPs and MTs, even if interactions between both proteins and their interaction with EB1 are also involved (Vaughan et al., 1999; Lansbergen et al., 2004; Akhmanova and Hoogenraad, 2005; Hayashi et al., 2005). The remarkable influence of the C-terminal tyrosine of tubulin on tubulin interaction with CAP-Gly + TIPs is reminiscent of a recent structural study of the interaction of EB1, which has the same C terminus as α-tubulin, with p150 Glued (Hayashi et al., 2005). In this study, the terminal tyrosine of the EB1 C terminus had a crucial contribution in EB1 interaction with the CAP-Gly domain of p150 Glued (Hayashi et al., 2005). Very recently, a similar role of the C-terminal tyrosine of EB1 has been reported in the case of EB1 interaction with CLIP-170 (Komarova et al., 2005). Such a conservation of the C-terminal tyrosine function is remarkable because the interaction of p150 Glued with tubulin involves several domains (Culver-Hanlon et al., 2006) and the interaction of EB1 with CLIP-170 also involves protein domains other than the EB1 C terminus (Busch and Brunner, 2004).

It is also remarkable that the role of the C-terminal aromatic residue of EB1 and of α-tubulin in regulating interactions with CAP-Gly + TIPs is conserved among organisms, from yeast to mammals, and may concern additional CAP-Gly proteins (Carvalho et al., 2003; Akhmanova and Hoogenraad, 2005). This may explain the conservation of the α-tubulin extreme C-terminal sequence, which has been intriguing, given that this tubulin sequence is not important for the 3D structure of the protein.

TTL-null cells offer a new and attractive system to evaluate the function of + TIPs’ interaction with MT. Within the framework of this study, we have restricted our analysis to the most obvious cellular phenotypes. We find that TTL suppression in fibroblasts compromises spindle positioning in cells placed on a micropatterned matrix. A recent study has shown that metaphase spindle positioning in cells growing on micropatterns depends both on the organization of the extracellular matrix, which is controlled by the micropattern, and on astral MT interactions with cues on the cell cortex (Thery et al., 2005). Such interactions are mediated by molecular complexes involving CLIP-170 (or CLIP-115) and p150 Glued (Busson et al., 1998; Coquelle et al., 2002). It is likely that the inhibition of CAP-Gly + TIPs’ interaction with detyrosinated astral MTs in TTL-null cells accounts for the impaired control of spindle positioning.

TTL suppression also affects the control of cell shape and of cellular extensions in fibroblasts. In fully detyrosinated cells (Tyr−), where CAP-Gly proteins do not interact with MT ends, cell polarization is diminished, and this agrees with previous work indicating a central role of CLIP-170 in MT-dependent regulations of actin assemblies (Fukata et al., 2002). In TTL-null cells containing enough Tyr tubulin to localize CAP-Gly + TIPs at MT ends, the cell morphology was still perturbed, with multiple cell extensions and an irregular shape. It may be that there are perturbations of CAP-Gly + TIPs’ function in cells where MTs are still extensively detyrosinated and where MT ends associate with diminished levels of CLIP-170 or that tubulin detyrosination affects proteins other than + TIPs. These possibilities are under examination in our laboratories.

What is the relationship of the phenotypes observed in TTL-null fibroblasts with the role of TTL in tumor progression and in brain development? Impaired control of spindle positioning has been proposed as one factor favoring tumor invasiveness (Vasiliev et al., 2004). In TTL-null tissues in mice, putative defects in spindle positioning due to tubulin detyrosination are apparently compensated, possibly through the action of geometrical constraints (Yu et al., 2000). The situation may be different in the brain, where TTL-null mice display a variable degree of ventricle enlargement, indicative of cell loss (Erck et al., 2005). Spindle positioning in neuronal progenitors is a complex and highly regulated process crucial for the control of progenitors’ proliferation/differentiation in the neuronal epithelium (Faulkner et al., 2000; Haydar et al., 2003). Spindle positioning could be perturbed in TTL-null mice with resulting abnormalities in neuronal differentiation/proliferation equilibrium. With regard to the control of cell morphology, our data are consistent with studies that indicate an important role of CAP-Gly + TIPs for the control of cell shape (Brunner and Nurse, 2000; Fukata et al., 2002; Gundersen, 2002). Such defects in cell shape control are apparently compensated in TTL-null nonneuronal tissues, which are apparently normal, whereas they are probably deleterious in neurons, which exhibit an erratic time course of neurite extensions (Erck et al., 2005). Neuronal cells may be especially sensitive to defects in cell shape controls, given the extreme size and complexity of neurite extensions. Finally, our data suggest that defects in cell shape may be associated with alterations of cell polarity. Such defects may affect cell motility as well as cell–cell or cell–matrix adhesions, which could be involved in the facilitating effect of tubulin detyrosination on tumor growth.

Our data demonstrate that tubulin tyrosination is required for MT interaction with CAP-Gly proteins but do not give definite clues to understand why a great number of eukaryotic cells developed a tyrosination cycle by introducing a detyrosination reaction. The bulk of tubulin is detyrosinated in differentiated cells (Gundersen and Bulinski, 1986), and it may be that tubulin detyrosination is used to disconnect MT–membrane interactions in terminally differentiated cells that do not need to change shape or to divide any longer. The identification of TCP and subsequent TCP suppression will be necessary for a full understanding of the tyrosination cycle. Clearly, though, this cycle is an important aspect of MT physiology, as it is involved in MT functions that are conserved, vital, and important for tumor progression.

Materials and methods

Antibodies

The following primary antibodies were used: Glu tubulin (Paturle-Lafanechere et al., 1994), Tyr tubulin (clone YL1/2; Wehland and Weber, 1987);
and fixed with 4% PFA/4.2% sucrose in PBS at 37 °C and PBS and first in freshly prepared embryos, either WT or TTL null. The experiments shown in the present paper were done using pooled fibroblasts from four different embryos, either WT or TTL null.

To visualize plus-end proteins, cultured fibroblasts were washed in warm PBS and exposed first in freshly prepared −20 °C methanol/1 mM EGTA, followed by 4% PFA/4.2% sucrose in PBS at room temperature (20 min for each step). To visualize actin, cells were washed in warm PBS and fixed with 4% PFA/4.2% sucrose in PBS at 37 °C, followed by cell permeabilization with 0.1% Triton X-100 in PBS. After incubation with primary antibodies, cells were incubated with Cy3, Cy5 (Jackson ImmunoResearch Laboratories), or Alexa 488 (Invitrogen) secondary antibodies. To visualize Factin, rhodamine-phallolidin (Invitrogen) was included with the secondary antibody. Lamellipodia were identified as cell extensions showing a strong marginal actin signal.

Images were captured with a charge-coupled device camera (CoolSNAP ES; Roper Scientific) in a straight microscopy (Axioskop 50; Carl Zeiss Microimaging, Inc.) controlled by MetaView software (Universal Imaging Corp.). When necessary, images were scanned using a piezo device adapted to different objectives in a straight microscope (Axioskop 50; Carl Zeiss Microimaging, Inc.) controlled by MetaView software (Universal Imaging Corp.).

Cell transfection
GFP–CLIP-170 cDNA was provided by F. Perez (Institut Curie, Paris, France); EB3-RFP was provided by V. Small (Institute of Molecular Biotechnology, Vienna, Austria); and GFP–CLIP-115 (Hoogenraad et al., 2000); GFP-p150 Glued (Hoogenraad et al., 2001); GFP-CLASP1 (Akhnmanova et al., 2001), and GFP-MCAK (Wordeman et al., 1999) have been described. Mouse TTL coding sequence was inserted in pcDNA3 (Invitrogen).

CLIP–HD–YFP (aa 1–278) was generated in pCINeo vector. His–CLIP-170 HD, with His–p150 Glued HD, was cloned into pET28 vector, were as described (Stepanova et al., 2003; Lansbergen et al., 2004).

To measure MT growth rate, we quantified EB3-RFP velocity in >30 cells for each phenotype. To analyze MT growth rates, we cultured MEFs in 35-mm glass Petri dishes (Iwaki). 48 h after cotransfection with GFP–CLIP-170 and EB3-RFP cDNAs, cells were maintained in DME 10% FBS and placed in a humidified incubator at 37 °C with 5% CO2 and 3% O2. The experiments shown in Figs. 1A and 1B were done with a 100 × 1.3 Plan-Neofluar oil objective and treated by deconvolution microscopy using a calculated point spread function.

We thank D. Proietto, A. Schweitzer, A. Popov, and C. Bosc for precious help during this work. We are grateful to Dr. F. Perez and Dr. V. Small for their advice and for providing CLIP-170 and EB3 constructions, respectively.

This work was supported primarily by a grant from Ligue Francaise contre le Cancer to D. Job (equipe labellisée Ligue) and in part by grants from the Netherlands Ministry of Economic Affairs and the Dutch Cancer Society to N. Gerin, a grant [GM62429] from the National Institutes of Health to L. Wordeman, and a grant from the Deutsche Forschungsgemeinschaft to J. Wetland. L. Peris is supported by a postdoctoral fellowship from the Fondation pour la Recherche Medicale.
