Ubiquitously expressed micro- and millicalpain, which both require the calpain small 1 (CAPNS1) regulatory subunit for function, play important roles in numerous biological and pathological phenomena. We have previously shown that the product of GAS2, a gene specifically induced at growth arrest, is an inhibitor of millicalpain and that its overexpression sensitizes cells to apoptosis in a p53-dependent manner (Benetti, R., G. Del Sal, M. Monte, G. Paroni, C. Brancolini, and C. Schneider. 2001. EMBO J. 20:2702–2714). More recently, we have shown that calpain is also involved in nuclear factor κB activation and its relative prosurvival function in response to ceramide, in which calpain deficiency strengthens the proapoptotic effect of ceramide (Demarchi, F., C. Bertoli, P.A. Greer, and C. Schneider. 2005. Cell Death Differ. 12:512–522). Here, we further explore the involvement of calpain in the apoptotic switch and find that in calpain-deficient cells, autophagy is impaired with a resulting dramatic increase in apoptotic cell death. Immunostaining of the endogenous autophagosome marker LC3 and electron microscopy experiments demonstrate that autophagy is impaired in CAPNS1-deficient cells. Accordingly, the enhancement of lysosomal activity and long-lived protein degradation, which normally occur upon starvation, is also reduced. In CAPNS1-depleted cells, ectopic LC3 accumulates in early endosome-like vesicles that may represent a salvage pathway for protein degradation when autophagy is defective.

Introduction

Macroautophagy, which is usually referred to as autophagy, is responsible for degradation of the majority of intracellular proteins in mammalian cells, particularly during starvation-induced proteolysis. Cytoplasmic proteins, organelles, and selected regions of the nucleus can be cleared by autophagy to ensure cellular homeostasis and remove damaged or unwanted products (Klionsky, 2005). Cytoplasmic constituents are first enclosed by a double-membrane autophagosome; next, the outer membrane of the autophagosome fuses with the lysosome, with the consequent destruction of the cargo and the inner membrane of the autophagosome by hydrolytic enzymes.

The autophagic pathway has been dissected at the molecular level in yeast, in which 27 genes, referred to as ATG, have been found to be required for autophagosome formation (Klionsky and Ohsumi, 1999; Yorimitsu and Klionsky, 2005). Two ubiquitin-like conjugation systems are involved in the process: one mediates the covalent attachment of Atg12 to Atg5, and the other mediates the conjugation of Atg8 to phosphatidylethanolamine (Ichimura et al., 2000). The resulting products, Atg12–Atg5 and Atg8-phosphatidylethanolamine, are essential for proper autophagosome formation. Only a small fraction of the Atg12–Atg5 complex localizes at the autophagic isolation membrane throughout elongation, and the complex dissociates when the phagosome is complete. On the other hand, Atg8 remains on the mature autophagosome constituting the recognized consensus marker of this structure. These two conjugation systems are highly conserved in mammalian cells. ATG5-deficient stem cells have been instrumental for demonstrating that the Atg12–Atg5 complex localizes at autophagosome precursors and plays an essential role in autophagosome formation (Mizushima et al., 2001). The production of ATG5-deficient mice has revealed that autophagy is required for neonatal...

Calpain is required for normal embryonic development. Indeed, the targeted disruption of CAPNS1 is embryonic lethal at days 10 and 11 as a result of severe defects in vascular development (Arthur et al., 2000). Calpain is a regulator of adhesive complex dynamics in adherent cells (Bhatt et al., 2002); it plays an important role in osteoclastic bone resorption (Hayashi et al., 2005) and is required for phagocytosis in human neutrophils (Dewitt and Hallett, 2002).

We have become interested in calpain function because of our observation that the product of GAS2, a gene specifically induced at growth arrest, is in fact an inhibitor of millicalpain and that its overexpression sensitizes cells to apoptosis in a p53-dependent manner (Benetti et al., 2001). More recently, we have shown that calpain is also involved in NF-κB activation and in its relative prosurvival function in response to ceramide, in which calpain deficiency strengthens the proapoptotic effect of ceramide (Demarchi et al., 2005). In this study, we further explore the involvement of calpain in the apoptotic switch and find that in calpain-deficient cells, autophagy is impaired with a resulting dramatic increase in apoptotic cell death.

Results
The lack of calpain activity is coupled to a block in autophagy
We have previously reported that calpain plays a crucial role in cell death regulation in response to ceramide. Indeed, we demonstrated that the lack of calpain activity results in a considerable

![Image](http://ag.arizona.edu/calpains). A homologue to CAPNS1, CAPNS2, has been described previously (Schad et al., 2002). This protein appears to be a functional equivalent to CAPNS1 in vitro; however, its in vivo function and tissue distribution are still controversial. Interestingly, ubiquitous calpains are associated with the endoplasmic reticulum and Golgi, a likely reservoir for autophagosome membranes (Hood et al., 2004), where the essential autophagy regulatory complex PI3K–Beclin also localizes (Kihara et al., 2001).

increase in apoptotic cell death (Demarchi et al., 2005). To further investigate the involvement of calpain in the modulation of alternative types of cell death, in this study, we address the role of calpain in autophagy. LC3 is the only available specific marker to detect autophagosomes in mammalian cells (Kabeya et al., 2000).

To directly tackle the question of whether calpain is required in autophagy, we analyzed endogenous LC3 in response to ceramide and rapamycin by means of immunofluorescence in wild-type and CAPNS1−/− mouse embryonic fibroblasts (MEFs). CAPNS1−/− MEFs, which are also known as calpain 4−/− MEFs, were derived from CAPNS1 (calpain 4) knockout mice and were shown to lack calpain activity (Arthur et al., 2000). Wild-type and CAPNS1−/− MEFs were induced with each stimulus for 3 h or were left untreated. Afterward, the cells were fixed and subjected to immunofluorescence analysis with an anti-LC3 antibody. As shown in Fig. 1 A (top), wild-type MEFs are faintly labeled by anti-LC3 antibody and show a clear induction of autophagosome formation after rapamycin or ceramide treatment. On the other hand, CAPNS1−/− MEFs show a higher diffuse background that does not substantially vary after stimulation with rapamycin or ceramide (Fig. 1 A, bottom).

In a parallel experiment, rapamycin and ceramide were used to stimulate wild-type and CAPNS1−/− MEFs, and the lysates were analyzed by Western blotting to detect both cytoplasmic LC3-I and its proteolytic derivative LC3-II that preferentially associates with autophagosomal membranes (Kabeya et al., 2004). In agreement with the immunofluorescence data, both rapamycin and ceramide trigger an increase of LC3II with respect to LC3I in wild-type cells, whereas the ratio between the two LC3 forms is not considerably altered by both stimuli in CAPNS1−/− MEFs (Fig. 1 B).

The fate of endogenous LC3 upon autophagy induction was also addressed in human U2OS cells. U2OS cells were transfected with a scrambled siRNA (siRNA control) or with a CAPNS1-specific siRNA. 72 h later, autophagy was induced by a 3-h incubation with ceramide, and the cells were either fixed and analyzed by immunofluorescence or lysed and subjected to Western blot analysis. As shown in Fig. 2 A, CAPNS1 depletion prevents the formation of bona-fide autophagosomes upon induction with ceramide. Accordingly, the increase in the endogenous membrane-bound LC3II after ceramide treatment is clearly defective after CAPNS1 silencing (Fig. 2 B).

**Calpain-deficient cells show a defect in lysosomal activation and long-lived protein degradation**

To further assess the requirement of calpain for the autophagic process, we followed the increase of lysosomal activity occurring...
after autophagy induction by means of LysoTracker staining and FACS analysis. Wild-type and CAPNS1−/− MEFs were incubated with rapamycin for 24 h, trypsinized, stained with LysoTracker green, and analyzed by FACS. The results obtained in a typical experiment are reported in Fig. 3 (A–D). A net increase in the percentage of cells that are highly labeled with LysoTracker occurs after rapamycin treatment of wild-type MEFs (Fig. 3 C) as compared with control untreated cells (Fig. 3 A), clearly showing that rapamycin results in an increase in lysosomal activity. On the contrary, in CAPNS1−/− MEFs, rapamycin is ineffective in inducing an increase in LysoTracker fluorescence intensity (Fig. 3, compare B with D). The mean values of the percentage of cells highly labeled by LysoTracker obtained in four independent experiments are reported in Fig. 3 E. To determine whether the increase in lysosomal activity was dependent on macroautophagy induction, 3-methyladenine (3MA) was added just before stimulation with rapamycin. 3MA clearly inhibits the increase in LysoTracker staining, indicating the specificity of the induction (Fig. 3 E). Next, other autophagic stimuli, namely etoposide, starvation in Earle’s balanced salt solution (EBSS) or serum-free medium, and ceramide, were used to induce autophagy in wild-type and CAPNS1−/− MEFs using the same type of assay. As shown in Fig. 3 F, all four stimuli induce autophagy-dependent lysosomal activation after 3 h in wild-type MEFs but not in CAPNS1−/− MEFs; moreover, the increase in LysoTracker labeling is dramatically reduced upon the addition of 3MA just before induction (Fig. 3 G).

To further investigate the requirement of calpain in autophagy, we monitored long-lived protein degradation upon amino acid starvation both in wild-type and CAPNS1−/− MEFs according to standard protocols (Pattingre et al., 2003). Amino acid starvation induces an increase in bulk protein degradation in both cell lines. However, such an increase is considerably lower in calpain-deficient cells as compared with wild-type cells (Fig. 3 H). A reduction in protein degradation occurs in the presence of the inhibitor 3MA in both cell lines, indicating that although considerably reduced, autophagy may still occur in CAPNS1−/− MEFs as a consequence of amino acid starvation. Alternatively, this result might be caused by an effect of 3MA on alternative degradation pathways, as a similar effect is also observed in autophagy-defective ATG5−/− cells (Mizushima et al., 2001). Similar results were obtained by studying long-lived protein degradation upon serum starvation (Fig. 3 I), confirming the importance of calpain in activating protein degradation through the autophagic process.

**Calpain is required for autophagosome formation in response to rapamycin**

Electron microscopy was used to directly analyze and quantify autophagosomes in wild-type and CAPNS1−/− MEFs grown in control serum-containing medium and after autophagy induction with rapamycin or amino acid–free medium (EBSS). The morphology of early autophagic vacuole (AV [AVi]) and late AV (AVd) profiles of wild-type MEFs are shown in Fig. 4 (A and B, respectively). The quantitative results obtained are represented in Fig. 4 C.

These electron microscopy experiments demonstrate that in CAPNS1−/− MEFs, autophagosome formation is completely abolished in response to rapamycin. In the case of EBSS-induced autophagy, CAPNS1−/− MEFs do show autophagosome formation but at a substantially reduced level compared with wild-type MEFs. In this last case, as shown in Fig. S2 (available at http://www.jcb.org/cgi/content/full/jcb.200601024/DC1), the morphology of the autophagosomes is not altered in CAPNS1−/− MEFs with respect to wild-type MEFs. This led us to conclude that the mechanics of autophagosome formation are still functional in CAPNS1−/− MEFs, however severely impaired in their efficiency. The diminished accumulation of autophagosomes in CAPNS1−/− MEFs maintained in EBSS medium may therefore suggest that the dramatic reprogramming of cell functions occurring upon amino acid deprivation may also involve the activation of some autophagic pathways not strictly requiring calpain function. Alternatively, because EBSS possibly represents a stronger and broader stimulus in respect to rapamycin, residual calpain activity caused by some other calpain isoforms may be sufficient to trigger autophagy, albeit at a reduced level.

This evidence prompted us to monitor Tor activity in both cell lines before and after rapamycin treatment using S6 kinase phosphorylation as readout. The results shown in Fig. S3 (available at http://www.jcb.org/cgi/content/full/jcb.200601024/DC1) clearly indicate that Tor is active in both cell lines, where it is inhibited with similar efficiency upon rapamycin addition.
Further studies are required to define the key regulatory elements targeted by calpain for the efficient induction of autophagosome formation.

Ectopic LC3 constitutively forms discrete bodies in calpain-deficient MEFs

A widely used method to study autophagy is monitoring the redistribution of the overexpressed autophagosome marker LC3 from a mostly diffused localization to a punctuated pattern upon the addition of an autophagic stimulus. Therefore, in parallel to the studies on endogenous LC3, we monitored autophagosome formation after overexpressed GFP-LC3 localization in wild-type and CAPNS1<sup>−/−</sup> MEFs. 16 h after transfection, the cells were preincubated with the macroautophagy inhibitor 3MA or solvent alone, and ceramide was added for 3 h to induce autophagy (Scarlatti et al., 2004). The cells were subsequently fixed to analyze overexpressed LC3 by fluorescence microscopy. As shown in Fig. 5 A, in wild-type MEFs, LC3 produces a mostly diffuse staining in the absence of stimulus and after 3MA treatment. After induction with ceramide, LC3 accumulates in the autophagosomes, whose formation is prevented by 3MA pretreatment, indicating the specificity of autophagy induction. However, in CAPNS1<sup>−/−</sup> MEFs, LC3 accumulates in specific bodies even under basal conditions; incubation with the autophagy inhibitor 3MA in this case does not prevent the formation of LC3 spots. In addition, the number of cells with intensely stained bodies does not substantially increase after the addition of ceramide (Fig. 5 B). Each experiment was repeated at least four times, obtaining reproducible results. For each experiment, the percentage of cells with LC3 bodies was counted, and the mean value ± SD is reported in the figure. At least 200 cells were analyzed for each independent experiment.

To further monitor autophagy induction, wild-type and CAPNS1<sup>−/−</sup> MEFs overexpressing GFP-LC3 were challenged with several stimuli that were previously used to induce autophagy, namely rapamycin (Noda and Ohsumi, 1998), amino acid–free medium (Neely et al., 1977), serum starvation (Pfeifer, 1973), and etoside (Shimizu et al., 2004). All of the treatments triggered autophagosome formation in wild-type MEFs (Fig. 5 C) while leaving unchanged the LC3 staining pattern in CAPNS1<sup>−/−</sup> MEFs (not depicted). Altogether, these results further suggest that autophagy is impaired in cells lacking calpain activity, where overexpressed LC3 constitutively accumulates into specific bodies.

Calpain silencing is coupled to the accumulation of overexpressed LC3 in human cells

To verify whether the constitutive accumulation of ectopic LC3 into the observed specific bodies in CAPNS1<sup>−/−</sup> MEFs was a peculiarity of the cell line used or a consequence of calpain inactivation, we monitored the effect of calpain silencing by siRNA on autophagosome formation in the human osteosarcoma cell line U2OS. An ATG5-specific siRNA that has been previously described (Boya et al., 2005) was used as a tool to prevent autophagy, allowing the distinction between true autophagosomes and other undefined structures containing ectopic LC3. U2OS cells were transfected with a scrambled siRNA (siRNA control) or with a CAPNS1-specific siRNA in combination with ATG5 siRNA or an ineffective siRNA as a control.

48 h later, the cells were transfected with GFP-LC3, and, after an additional 16 h, autophagy was induced by a 3-h incubation with ceramide. The fixed cells were finally analyzed by fluorescence microscopy. As shown in Fig. 6 A, LC3 appears diffuse in control U2OS cells and, after induction with ceramide, becomes associated with autophagosomes, which are not formed by specifically inhibiting autophagy through ATG5 siRNA. On the other hand, CAPNS1-silenced U2OS cells show LC3-positive bodies in the absence of stimulation, and the distribution of GFP-LC3 is not altered by ATG5 silencing. In addition, the LC3 staining pattern is not considerably affected by ceramide (Fig. 6 B).

To mark and analyze the LC3 pattern specifically in the cells where CAPNS1 is silenced, we developed an siCAPNS1-GFP p-superior plasmid (siCAPNS1-GFP) allowing the simultaneous expression of CAPNS1 siRNA and GFP. In parallel, we produced a U2OS-derivative cell line expressing HcRed-LC3 (U2OS-LC3) as a tool to study autophagy induction. U2OS-LC3 cells were transfected with a control vector (sicontrol-GFP) or with siCAPNS1-GFP plasmid; after 48 h, they were stimulated or left unstimulated with ceramide for 3 h and were fixed and analyzed by fluorescence microscopy.

As shown in Fig. 6 C, in the cells transfected with the control plasmid, HcRed-LC3 appears diffuse before induction and forms autophagosomes after ceramide treatment as expected. However, siCAPNS1-GFP–transfected cells show a punctuated LC3 pattern both in the presence and absence of ceramide stimulation. Collectively, the data obtained in U2OS cells are in agreement with the data obtained comparing wild-type
with CAPNS1−/− MEFs, demonstrating that in CAPNS1-depleted cells, overexpressed LC3 accumulates in specific bodies independently of autophagy induction.

**Ectopic LC3 bodies constitutively present in CAPNS1-depleted cells are enriched in endosome markers**

To investigate the identity of LC3-containing structures in CAPNS1-depleted cells, we analyzed whether overexpressed LC3 would eventually colocalize with specific endosomal markers both in control and in CAPNS1-silenced U2OS-LC3 cells. 48 h after silencing with control or CAPNS1 siRNA, autophagy was induced by ceramide together with pepstatin to inhibit lysosomal activity and freeze any eventual transient colocalization event. Thereafter, the cells were fixed and analyzed by fluorescence microscopy. The different patterns of GFP::LC3 distribution were scored in 250 transfected cells for at least three independent experiments. Bar, 20 μm.

To precisely define the identity of the LC3-positive bodies that accumulate in calpain-deficient cells, immuno-electron microscopy studies were performed. U2OS cells were transfected with GFP-LC3 and siRNA specific for CAPNS1 as described in the first section of Results and were fixed in PFA. Double labeling with GFP and LAMP-2 antibodies allowed us to detect GFP-LC3 bodies and also mark endosomes in the same experiment. As expected, GFP-LC3 partly accumulates in specific bodies, as shown in Fig. 8 (A and B). The gold particles indicating the presence of GFP-LC3 bodies (Fig. 8, large gold dots) were associated with endosome-like structures, some of which were also positive for LAMP-2 (Fig. 8; small gold dots are indicated by arrowheads). The morphology and LAMP-2 labeling pattern of GFP-LC3 structures corresponded to that of early endosome-like vesicles, clearly confirming that GFP-LC3 bodies accumulating in CAPNS1-depleted cells are not autophagosomes.
The calpain-dependent impairment of autophagy sensitizes cells to apoptosis

We have previously reported that ceramide triggers apoptosis and induces an NF-κB–dependent prosurvival pathway through calpain. Accordingly, in calpain-deficient cells, apoptosis is enhanced (Demarchi et al., 2005). In this study, we have demonstrated that calpain is required to induce autophagy in response to ceramide, etoposide, and amino acid or serum starvation. Recent studies indicate the existence of a negative cross-regulation between autophagy and apoptosis (Yu et al., 2004; Boya et al., 2005; Takacs-Vellai et al., 2005). However, there are examples of a mutual requirement between the two pathways (Camougrand et al., 2003; Martin and Baehrecke, 2004). Therefore, we decided to define the effect of the calpain-related autophagy block on apoptosis induction in the cellular systems used for this study.

Wild-type and CAPNS1−/− MEFs were incubated with the autophagy inducers etoposide, ceramide, serum-free medium, EBSS, or vinblastine for 20 h. Afterward, the cells were double labeled with annexin V and propidium iodide (PI) and were analyzed by FACS. The results obtained in a typical experiment of EBSS induction are reported in Fig. 9 (A–D). The histogram presented in Fig. 9 E summarizes the results of four independent experiments for each specific stimulus. A dramatic increase in apoptosis can be seen in calpain-deficient cells after induction with all of the stimuli, with the exception of vinblastine. Vinblastine is a microtubule-depolymerizing agent, and, although it can trigger an autophagic response, it has inhibitory functions on late autophagic events (Punnonen and Reunanen, 1990). Interestingly, we have previously reported that the toxicity of taxol, an indirect inhibitor of autophagy by virtue of its block of microtubule depolymerization, is almost comparable in wild-type and CAPNS1−/− MEFs (Demarchi et al., 2005). Collectively, the aforementioned data highlight the cytoprotective potential of autophagy in MEFs and strongly argue for a strict correlation between the impairment of autophagy in calpain-deficient cells and induction of the apoptotic switch.

To further confirm this hypothesis, a similar approach was followed using human U2OS cells silenced either with ATG5, CAPNS1-specific siRNA, or a combination of the two. 48 h after silencing, the cells were shifted to amino acid–free medium and incubated for a further 20 h to trigger autophagy. Cell death was then quantified by means of PI and annexin staining followed by FACS analysis. Fig. 10 (A–F) presents the results of a representative experiment and indicates that both ATG5 and CAPNS1 silencing sensitize U2OS cells to apoptosis induced by amino acid starvation. The mean values obtained in four independent experiments are reported in Fig. 10 G. The effect of CAPNS1 silencing is the most severe, suggesting that CAPNS1 depletion in addition to the block of autophagy also prevents other antiapoptotic mechanisms such as NF-κB activation (Demarchi et al., 2005).

Discussion

In this study, we demonstrate that calpain regulates macroautophagy in two cellular systems lacking calpain activity: MEFs derived from CAPNS1 knockout mice and CAPNS1-silenced
human cells. In addition, we shed some light on the relationship between apoptosis and autophagy.

Calpains are activated by several stimuli that trigger macroautophagy, including starvation (Gomez-Vicente et al., 2005), ceramide (Tanabe et al., 1998; Demarchi et al., 2005), etoposide (Varghese et al., 2001), and arsenic trioxide (Karlsson et al., 2000). Milli- and microcalpain, which both require CAPNS1 for activity, are localized at the endoplasmic reticulum and Golgi, where the autophagic machinery works (Kihara et al., 2001; Pattingre et al., 2005).

In both calpain-null systems used in this study, deficient autophagy was shown by four different approaches: analysis of exogenous and endogenous LC3 by immunofluorescence and Western blotting, quantification of lysosomal induction, long-lived protein degradation assays, and electron microscopy. Altogether, the data presented indicate that in CAPNS1-deficient cells, the autophagic program is not efficiently activated. As a result of this defect, CAPNS1-deficient cells are more sensitive to apoptosis induced by several autophagic stimuli, including ceramide, etoposide, and starvation.

In light of our findings connecting calpain and autophagy, it will be interesting to investigate this relationship in vivo under physiological and pathological conditions as well as in response to chemotherapy. Previously reported data lend support to such a possibility. The dual role of autophagy has been seen during cancer progression, where, at the initial stages, autophagy prevents tumor growth (Liang et al., 1999), whereas at advanced stages, it might favor tumor cell survival (Paglin et al., 2001). An example of this is calpain 9, which appears to be a tumor suppressor of gastric cancer, whereas calpain activation has been shown to be involved in cell transformation and invasion (Carragher and Frame, 2002; Xu and Deng, 2004).

Most interestingly, this parallel is maintained in other degenerative pathologies. Autophagy is protective during the initial stages of neurodegeneration (Webb et al., 2003; Ravikumar et al., 2004), whereas it becomes deleterious at later stages (Yue et al., 2002). A similar dual role could be played by calpain in neuronal diseases, where it may be protective at the initial stages of neurodegeneration (Kim et al., 2003) and hyperactivated and detrimental at advanced stages (Park and Ferreira, 2005). A detailed investigation of the molecular cross talk between these two systems in living organisms might be instrumental for performing appropriate strategies of molecular intervention.

The precise molecular network linking autophagy, apoptosis, and other types of cell death is still unresolved (Assuncao Guimaraes and Linden, 2004; Kroemer and Jaattela, 2005). Autophagy is protective against low radiation damage (Paglin et al., 2001) and against mutant huntingtin-induced cell death (Bjorkoy et al., 2005); it is essential for maintaining cell survival after growth factor withdrawal in Bax−/−Bak−/− cells (Lum et al., 2005). Furthermore, the inhibition of macroautophagy triggers apoptosis (Boya et al., 2005; Gonzalez-Polo et al., 2005). On the other hand, autophagy is coupled to cell death in Bax−/−Bak−/− MEFs (Shimizu et al., 2004) and in tamoxifen-treated MCF7 cells (Bursch et al., 2000). In addition, autophagy and apoptosis are positively interconnected in several systems, including Drosophila development (Baehrecke, 2003), rat retinal tissue development (Guimaraes et al., 2003), and peripheral nerves of adult rats after damage (Xue et al., 1999). Collectively, our data further support the argument that macroautophagy is a survival strategy activated both in response to serum and amino acid deprivation. In addition, we have shown that macroautophagy is activated and also plays a protective role upon treatment with specific drugs, such as etoposide and ceramide; thus, the knockdown of autophagy could be a strategy for improving chemotherapy protocols.

Ectopic LC3 is a powerful tool to study autophagy (Kabeya et al., 2000). In this study, we confirmed that in MEFs and U2OS human osteosarcoma cells, the formation of LC3 autophagosomes is efficiently inhibited by treatment with the autophagy inhibitor 3MA and by siRNA-mediated depletion of the essential autophagy gene ATG5, respectively. However, in CAPNS1−/− MEFs and siCAPNS1-depleted cells, we observed that ectopic LC3 constitutively accumulates in the absence of any specific autophagic stimulus into cytoplasmic endosome-like bodies enriched with endosomal markers. Therefore, we hypothesize that such LC3 bodies could represent a default or salvage lysosomal pathway for protein degradation with slower clearance kinetics, which becomes manifest in a calpain-deficient cellular context. A similar pathway may be predicted for the endogenous proteins that accumulate in diseases coupled to autophagy defects.
Further studies are required to analyze the detailed mechanisms involving calpains in the formation of autophagosomes and in lysosomal-mediated protein degradation pathways. Given the strategic localization of milli- and microcalpain at the endoplasmic reticulum, it would be tempting to speculate that calpain may play a role in the delivery of membranes to the autophagosome. Alternatively, calpain could modulate one or more key components of the signaling networks, ultimately leading to autophagosome formation. The complete block of autophagosome formation occurring in rapamycin-treated CAPNS1−/− MEFs favors such a possibility.

Materials and methods

Chemicals and reagents

C2 ceramide, bafilomycin, pepstatin A, 3MA, rapamycin, and etoposide were purchased from Sigma-Aldrich. LipofectAMINE reagent and Oligo-fectamine were purchased from Invitrogen. SMARTpool for CAPNS1 silencing was obtained from Dharmacon. Micro- and millicalpain siRNAs were purchased from Santa Cruz Biotechnology, Inc.

Plasmids and constructs

HcRed-hLC3 and pGFP-hLC3 were constructed by inserting human LC3 in HcRed and pGFP plasmid, respectively. The plasmid pGFP-rLC3 was a gift from T. Yoshimori (National Institute of Genetics, Shizouka, Japan). The plasmid scCAPNS1-pGFP was obtained by subcloning a double-stranded oligonucleotide containing a sequence complementary to CAPNS1 siRNA into commercial pSuperior–GFP plasmid according to the manufacturer’s instructions. All constructs were checked by sequence analysis.

Cell culture

Wild-type and CAPNS1−/− MEFs (Dourdin et al., 2001) were gifts from P.A. Greer (Queen’s University, Kingston, Ontario, Canada). U2OS cells and the aforementioned mouse fibroblasts were grown in DME supplemented with 10% FCS.

Immunological procedures and quantifications

Standard protocols for immunoblotting and immunofluorescence were used. Rabbit serum raised against LC3 was provided by T. Yoshimori. Monoclonal antibody against LAMP-2 was purchased from BD Biosciences. Rabbit serum raised against LC3 was provided by T. Yoshimori. Standard protocols for immunoblotting and immunofluorescence were adopted for access to FACS and the confocal microscope.

Electron microscopy

Monolayers were fixed in 2% glutaraldehyde in 0.2 M Hepes, pH 7.4, for 2 h and were scraped off the dish during fixation. The pellets were embedded in Epon using routine procedures. Approximately 60-nm sections were cut and stained using uranyl acetate and lead citrate and were examined with an electron microscope (JEM 1200EXII; JEOL). The number of AVi and AVd profiles was counted under the microscope by systematically screening the sections at 12,000× using grid squares as sampling units, as previously described (Eskelinen et al., 2004).

Online supplemental material

We are grateful to Stefania Mastroianni for technical support, Peter Greer for providing CAPNS1−/− MEFs, and Tatsuro Yoshimori for the gifts of anti-LC3 antibody and GFP-LC3 plasmid. We thank Francesca Scarlatti (S. Paolo Medical School, Milan, Italy) and Patrizia Cologno (Institut National de la Santé et de la Recherche Médicale, Villejuif, France) for providing protocols and useful suggestions and Georgine Foulkner (The International Centre for Genetic Engineering and Biotechnology [ICGEB], Trieste, Italy) for critically revising the manuscript. We are grateful to Maura Giacco [ICGEB] for access to FACS and the confocal microscope.

This work was supported by grants AfnC R1214, MIUR FIRB2001, and MIUR PRIN2004 to C. Schneider. C. Bertoli is a recipient of a fellowship from FIR. T. Copetti is a student at the International School for Advanced Studies (Trieste, Italy).
