Introduction

The plasma membrane of polarized columnar-shaped epithelial cells is segregated into functionally distinct apical and basolateral domains that face different biological compartments and regulate vectorial transport of ions and solutes. Biogenesis of these membrane domains and maintenance of cell shape depend on protein sorting during vesicle budding from the TGN and endosomes, transport of vesicles along the actin and microtubule cytoskeleton, and their fusion with the appropriate membrane domain (Griffiths and Simons, 1986; Matter and Mellman, 1994; Mostov et al., 2000; Rodriguez-Boulan et al., 2005).

The microtubule cytoskeleton is involved in long-range transport of vesicular carriers and in the morphogenesis of columnar-shaped, polarized epithelial cells (Musch, 2004). During polarization, microtubules are organized into a vertical network that orients along the apicobasal cell axis (Musch, 2004; Rodriguez-Boulan et al., 2005). TGN-derived vesicular carriers associate with microtubules (Van der Sluijs et al., 1990; Hirschberg et al., 1998; Toomre et al., 1999), and disruption of the microtubule cytoskeleton and its motor proteins reduces the efficiency of apical and basolateral protein delivery to their respective membrane domains (Rindler et al., 1987; Lafont et al., 1994; Grindstaff et al., 1998; Kreitzer et al., 2000; Jaulin et al., 2007). How release and transport of vesicles from the Golgi complex to the plasma membrane are coordinated with microtubule organization is unknown.

In the budding yeast *Saccharomyces cerevisiae*, polarized membrane growth is spatiotemporally coordinated by septins (Barral et al., 2000; Gladfelter et al., 2001), a family of filamentous GTPases that associate with cell membranes and the cytoskeleton (Spiliotis and Nelson, 2006). In mammalian cells, septins bind to microtubules (Surka et al., 2002; Nagata et al., 2003; Spiliotis et al., 2005), but the functional significance of this association in interphase cells and the role of septins in the morphogenesis of polarized epithelia are unknown. Here, we examine the distribution and function of the mammalian SEPT2 with respect to the microtubule cytoskeleton of Madin-Darby canine kidney (MDCK) cells. We show that SEPT2 associates with a distinct subset of microtubule tracks and is required for efficient Golgi-to-plasma membrane transport and the morphogenesis of columnar-shaped epithelial cells.

Epithelial polarity requires septin coupling of vesicle transport to polyglutamylated microtubules

n epithelial cells, polarized growth and maintenance of apical and basolateral plasma membrane domains depend on protein sorting from the trans-Golgi network (TGN) and vesicle delivery to the plasma membrane. Septins are filamentous GTPases required for polarized membrane growth in budding yeast, but whether they function in epithelial polarity is unknown. Here, we show that in epithelial cells septin 2 (SEPT2) fibers colocalize with a subset of microtubule tracks composed of polyglutamylated (polyGlu) tubulin, and that vesicles containing apical or basolateral proteins exit the TGN along these SEPT2/polyGlu microtubule tracks. Tubulin-associated SEPT2 facilitates vesicle transport by maintaining polyGlu microtubule tracks and impeding tubulin binding of microtubule-associated protein 4 (MAP4). Significantly, this regulatory step is required for polarized, columnar-shaped epithelia biogenesis; upon SEPT2 depletion, cells become short and fibroblast-shaped due to intracellular accumulation of apical and basolateral membrane proteins, and loss of vertically oriented polyGlu microtubules. We suggest that septin coupling of the microtubule cytoskeleton to post-Golgi vesicle transport is required for the morphogenesis of polarized epithelia.
Results and discussion

Immunofluorescence microscopy of nonpolarized MDCK cells with antibodies to SEPT2 and the Golgi resident protein p115 revealed a juxtanuclear tuft of SEPT2 fibers closely apposed to the Golgi complex (Fig. 1, A and B). SEPT2 fibers co-aligned with microtubules (Fig. S1 A, available at http://www.jcb.org/cgi/content/full/jcb.200710039/DC1), and their distribution was dependent on microtubule structural integrity (Fig. S1 B). Because formation and transport of Golgi-derived vesicles occur along microtubules (Hirschberg et al., 1998; Toomre et al., 1999), we determined if SEPT2 localized to sites of vesicle export from the Golgi complex. We used high resolution live-cell imaging of MDCK cells that stably expressed a YFP-tagged SEPT2 at sub-endogenous levels (Spiliotis et al., 2005) and transiently co-expressed marker proteins of either the apical (CFP-tagged glycosyl phosphatidylinositol [gpi] or neurotrophin receptor protein 75 [p75]) or basolateral membrane (CFP-tagged vesicular stomatitis virus G protein [VSV-G] or low density lipoprotein receptor [LDL-R]). Note that SEPT2-YFP fibers colocalized with microtubules around the TGN similar to endogenous SEPT2 (Fig. 1 F).

Strikingly, the majority of tubular–vesicular carriers containing apical (Fig. 1 C; Video 1 and Fig. S2, B and D) or basolateral marker proteins (Fig. S2, C and E) exited the Golgi complex along SEPT2-YFP fibers (Fig. 1 E). In contrast, membrane tubules containing a TGN resident protein (galactosyltransferase; GalTase) rarely overlapped with SEPT2-YFP fibers (Fig. 1, D and E; Video 2; Fig. S2 A).

In some instances SEPT2-YFP was not static but traversed the cytoplasm as tubular–vesicular elements (Video 3) with instantaneous velocities (0.38 ± 0.16 μm/s; n = 33) similar to those of kinesin-driven vesicles (Toomre et al., 1999). Consistent with this observation, and with septin binding to membrane phosphoinositides (Zhang et al., 1999) and synaptic vesicles (Beites et al., 1999), SEPT2 cofractionated with vesicle membranes that contained exocytic cargo (E-cadherin) and the small GTPase Rab8 (Fig. S3). SEPT2 also colocalized with Golgi-derived membrane tubules induced by expression of the inactive form of protein kinase D1 (PKD-K618N; Fig. 1 G), which blocks fission from the TGN of vesicles that are specifically destined for the plasma membrane (Liljedahl et al., 2001).

To test if SEPT2 is required for vesicle transport from the TGN to the plasma membrane, SEPT2 organization was disrupted by microinjecting cells with anti-SEPT2 IgGs and examining the effects on trafficking of the basolateral membrane marker VSV-G (ts045-VSV-G-YFP) and the apical membrane marker p75-GFP. In the presence of anti-SEPT2 IgGs, delivery the entire image to enhance the fluorescence intensity of tubular–vesicular structures. Arrows point to tubular vesicular elements extending from the Golgi complex. (E) Tubular–vesicular carriers containing CFP-tagged gpi, GalTase, VSV-G, and p75 were scored for overlap with SEPT2-YFP fibers (n = 80–100; mean values ± SEM from three independent experiments). (F) 3D-rendered confocal images of a Golgi region from MDCK-SEPT2-YFP cells stained with α-tubulin and furin convertase antibodies. (G) HeLa cells were transfected with the protein kinase D1 mutant PKD-K618N (PKD1-KD) tagged with GST. Cells were stained with GST and SEPT2 antibodies. Arrowheads point to a PKD-K618N-containing tubular extension. Bars, ~5 μm.

Figure 1. SEPT2 fibers localize to TGN sites of apical and basolateral protein export. (A and B) Subconfluent monolayers of MDCK cells were stained with SEPT2 and p115 antibodies, and imaged by confocal microscopy. Optical sections from the bottom, middle, and top of the highlighted Golgi region are shown at higher magnification [B]. [C and D] MDCK-SEPT2-YFP cells were transiently transfected with gpi-CFP or GalTase-CFP, and imaged by time-lapse microscopy at 37°C. Non-neighbor deconvolution was applied and linear dynamic ranges were renormalized equally across.
of ts045-VSV-G-YFP (Fig. 2, A and C) and p75-GFP (Fig. 2, B and D) from the Golgi to the plasma membrane was greatly reduced compared with that in the presence of control IgGs.

Co-alignment of SEPT2 with microtubules near the TGN (Fig. 1 F and Fig. S1 A) raised the possibility that SEPT2 might enhance vesicle transport on a qualitatively and/or functionally distinct subset of microtubule tracks. Immunofluorescence with antibodies to acetylated and detyrosinated tubulin revealed little or no colocalization between these post-translationally modified microtubules and SEPT2 fibers (unpublished data). In contrast, the preponderance of juxtanuclear/Golgi-proximal SEPT2 fibers colocalized with microtubules composed of polyglutamyalted (polyGlu) tubulin (Fig. 3 A), which contains C-terminal side chains with 2–6 glutamate residues (Edde et al., 1990). When levels of SEPT2 were reduced by SEPT2 siRNAs, there was a concomitant decrease in the level of polyGlu microtubules (Fig. 3, B and E), indicating that SEPT2 is required for the maintenance of polyGlu microtubules. To further test whether SEPT2 is required for tubulin polyglutamylation, SEPT2 was buffered away from microtubules by overexpressing its cytoplasmic binding partner MAP4-GFP (Kremer et al., 2005). Excess cytoplasmic MAP4-GFP (high levels of expression; Fig. 3 D) or MAP8 (unpublished data) light chains did not disrupt SEPT2 fibers or polyGlu microtubules.

We next examined whether loss of SEPT2 fibers and polyGlu microtubules affected vesicular transport between the Golgi and the plasma membrane. Indeed, loss of SEPT2 fibers and polyGlu microtubule tracks upon MAP4-GFP overexpression resulted in decreased delivery of ts045-VSV-G-YFP to the
septins in sequestering MAP4 from microtubules (Kremer et al., 2005), which controls the stability of microtubules, microtubule-associated SEPT2 is required for the maintenance of a distinct subset of microtubules (polyGlu microtubules) that facilitate efficient vesicle transport.

To further examine whether the polyGlu side chains of tubulin or polyGlu tubulin-bound SEPT2 directly affect MAP4–tubulin binding, we used a competitive blot overlay assay, which has been used previously to map tubulin binding sites of motors and MAPs and quantitatively examine the effect of tubulin polyglutamylation on their binding (Larcher et al., 1996; plasma membrane (Fig. 3 G). Direct disruption of SEPT2 fibers in cells cotransfected with SEPT2 siRNAs and ts045-VSV-G-YFP also reduced Golgi-to-plasma membrane transport of VSV-G (ratio of plasma membrane [PM] to intracellular [IC] fluorescence of 0.6 ± 0.04 [n = 21] vs. 1 ± 0.1 [n = 9] in control cells; P < 0.0001). However, cotransfection of a mixture of SEPT2 and MAP4 siRNAs resulted in an intermediate VSV-G delivery phenotype (PM:IC fluorescence 0.81 ± 0.1 [n = 22]; P < 0.003), indicating that SEPT2 and MAP4 counteract each other in regulating vesicle transport along microtubules. Therefore, in addition to the previously characterized role of cytoplasmic septins in sequestering MAP4 from microtubules (Kremer et al., 2005), which controls the stability of microtubules, microtubule-associated SEPT2 is required for the maintenance of a distinct subset of microtubules (polyGlu microtubules) that facilitate efficient vesicle transport.

To further examine whether the polyGlu side chains of tubulin or polyGlu tubulin-bound SEPT2 directly affect MAP4–tubulin binding, we used a competitive blot overlay assay, which has been used previously to map tubulin binding sites of motors and MAPs and quantitatively examine the effect of tubulin polyglutamylation on their binding (Larcher et al., 1996;
Having shown that SEPT2 plays roles in vesicular transport, we tested whether SEPT2 is required for the establishment of epithelial membrane polarity and columnar cell shape. We depleted endogenous SEPT2 from nonpolarized, "contact-naïve" MDCK cells with siRNAs, and then assayed cell polarity and shape in monolayers of polarized cells grown on filters (Fig. 5, A and B). In contrast to the columnar morphology of cells treated with control siRNAs, SEPT2-depleted cells lacked an apical dome and honeycomb morphology characteristic of a polarized, columnar epithelium (Fig. 5 C). Significantly, SEPT2-depleted cells were elongated along their long axis and were shorter compared with control cells (Fig. 5 D). These defects
Na/K-ATPase shifted toward fractions of low buoyant density ($\rho = 1.03–1.08$ g/ml) compared with controls. These fractions did not contain the TGN resident protein furin (Fig. 5 J) and their low densities resembled those of post-Golgi vesicle membranes (Wandinger-Ness et al., 1990; Deretic and Papermaster, 1991), which is consistent with the accumulation of gp135/podocalyxin and Na/K-ATPase in punctate intracellular structures (Fig. 5 G). Note that caveolin, which traffics from the Golgi to both the apical and basolateral membranes in stable microdomains distinct from the dynamic mechanisms of vesicle formation that characterize most membrane proteins (Tagawa et al., 2005), was unaffected by SEPT2 depletion (Fig. 5 J).

Based on these data, we suggest that SEPT2 is required for efficient Golgi-to-plasma membrane transport of vesicles correlated with a lack of vertically oriented polyGlu microtubules; note that in columnar-shaped control cells polyGlu microtubules colocalized with SEPT2 fibers parallel to the lateral membrane in the apicobasal axis (Fig. 5 E). Moreover, in SEPT2-depleted cells, levels of endogenous apical (gp135/podocalyxin) and basolateral (Na/K-ATPase) membrane markers were significantly reduced from their respective membrane domains (Fig. 5, F and I), and these proteins accumulated intracellularly in punctate structures (Fig. 5, G and H); this was not due to loss of the diffusion barrier between the apical and basolateral membrane domains as tight junctions were unaffected in SEPT2-depleted cells (unpublished data). In OptiPrep density gradients of membranes from control and SEPT2 siRNA-treated cells (Fig. 5 J), the distribution of membranes containing gp135/podocalyxin and Na/K-ATPase shifted toward fractions of low buoyant density ($\rho = 1.03–1.08$ g/ml) compared with controls. These fractions did not contain the TGN resident protein furin (Fig. 5 J) and their low densities resembled those of post-Golgi vesicle membranes (Wandinger-Ness et al., 1990; Deretic and Papermaster, 1991), which is consistent with the accumulation of gp135/podocalyxin and Na/K-ATPase in punctate intracellular structures (Fig. 5 G). Note that caveolin, which traffics from the Golgi to both the apical and basolateral membranes in stable microdomains distinct from the dynamic mechanisms of vesicle formation that characterize most membrane proteins (Tagawa et al., 2005), was unaffected by SEPT2 depletion (Fig. 5 J).
containing apical or basolateral membrane proteins. This is supported by: (1) presence of SEPT2 at TGN sites of plasma membrane protein export (Fig. 1); (2) decreased post-Golgi vesicle traffic in nonpolarized MDCK cells upon microinjection of function-blocking SEPT2 antibodies (Fig. 2); and (3) reduced membrane growth (Fig. 5, G and H) and columearization (Fig. 5, C and D) of MDCK cell monolayers upon SEPT2 depletion. Although SEPT2 is involved in microtubule-dependent vesicle transport at TGN exit sites, we cannot exclude the possibility that SEPT2 also functions in vesicular transport from and to post-Golgi compartments (e.g., recycling endosomes) en route to the plasma membrane. Recent studies indicate that apical and basolateral proteins traffic through transport intermediates upon exit from the TGN (Ang et al., 2004; Fields et al., 2007; Gravotta et al., 2007). Interestingly, SEPT2 localization to endosomes and cell–cell junctions has been observed in MDCK cells by immuno-EM (unpublished data). Future studies will test whether septins regulate vesicle transport at these sites of membrane fusion and fusion.

Similar to the Ras-like (e.g., Rab, Rho/Rac) and myosin-kinesin superfamilies of P-loop NTPases, septins comprise a unique superfamily of GTPases (Leipe et al., 2002). Although cytoplasmic septin complexes have been shown to have the ability to regulate microtubule stability (Kremer et al., 2005), the function of the microtubule-associated, filamentous septins is unknown. We suggest that SEPT2 regulates the efficiency of vesicle transport by antagonizing MAP4, whose inhibitory role in vesicle transport is independent of its role in microtubule stability (Bulinski et al., 1997). Because microtubule-associated proteins inhibit the binding of TGN-derived vesicles to microtubules in vitro (Van der Sluijs et al., 1990) and membrane motility and traffic in vivo (Bulinski et al., 1997), we suggest that SEPT2 binding to poly-glutamylated microtubules specifies a functionally distinct subset of microtubule tracks on which “fast track” vesicle transport occurs without the impediment of MAP “speed bumps.” Therefore, the balance between the levels of polyGlu microtubules, SEPT2, and MAP4 may control the amount of vesicle transport to the plasma membrane. For example, different amounts of vesicle transport may be required for rapid membrane growth during morphogenesis of a columnar epithelium compared with those required to maintain homeostasis or in response to physiological stress (wound healing). This type of regulation may be important in other cell types, as microtubule-dependent vesicle transport in neurons requires polyGlu microtubules (Ikegami et al., 2007) and the dissociation of MAPs from microtubules (Mandekow et al., 2004).

Materials and methods

Cell culture and DNA constructs

Helo and MDCK clone II cells were maintained as described previously (Spiliotis et al., 2005). The plasmid vector encoding for ts045-VSVG3-SP-cherry was constructed by subcloning mCherry into pVSVG3-SP-YFP-N1 (a gift from K. Simons, Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany).

Plasmid DNA and siRNA transfections

Plasmids for ts045-VSVG3-SP-cherry, GST-tagged PKD1-K618N (a gift from Y. Yang; Stanford University, Stanford, CA) were transfected using the Lipofectamine 2000 reagent (Invitrogen). MDCK cells were transfected with siCONTROL nontargeting siRNA #1 (Dharmacon RNA Technologies), MAP4 (ON-TARGET plus SMART pool; Dharmacon RNA Technologies), and SEPT2 siRNA oligonucleotides as described previously (Spiliotis et al., 2005).

Immunofluorescence microscopy

Subconfluent cell monolayers (Figs. 1, 3, and S1) were fixed with warm PHEM (60 mM Pipes-KOH, pH 6.9, 25 mM Hepes, 10 mM EGTA, and 1 mM MgCl₂ containing 3% paraformaldehyde (PFA; EM Sciences) and 0.1% Triton X-100, and stained with antiserum to SEPT2 (N5N; rabbit polyclonal, a-tubulin (DM1A; Sigma-Aldrich), p115 (a gift from S. Pfeffer; Stanford University), furin convertase [ABR], GST (nAb B-14; Santa Cruz Biotechnology, Inc.), polyglutamylated tubulin (IgM clone B3; Sigma-Aldrich), FLAG (nAb M2; Sigma-Aldrich), and with secondary FITC- or Rhodamine red X-conjugated (Fab′) goat or donkey anti-mouse and anti-rabbit IgGs, Rhodamine red X-conjugated (Fab′) goat anti-mouse IgM and Cy5-conjugated (Fab′) donkey anti-rabbit IgG (Jackson ImmunoResearch Laboratories).

Confluent MDCK monolayers grown on Transwell filters (Figs. 5 and S4) were fixed in PBS containing 3% PFA and stained with antibodies to SEPT2, gp135/podocalyxin [3F2/D8 mouse hybridoma supernatant], and Na/K-ATPase (chicken polyclonal; Novus). To stain for a-tubulin and polyGlu tubulin (Fig. 5, C and E), cells were fixed with warm microtubule stabilizing buffer (80 mM Pipes-KOH; pH 6.8, 5 mM EGTA; and 2 mM MgCl₂) containing 0.5% Triton X-100 and 0.3% glutaraldehyde (EM Sciences).

Samples were imaged in Vectashield mounting medium (Vector Laboratories) with a confocal laser scanning microscope (LSM 510; Carl Zeiss, Inc.) by obtaining 0.4–0.8-μm optical sections with a 100×1.4 NA oil objective. Fluorescence quantifications (Fig. 3) were performed after importing LSM images into Slidebook 4.2 software (Intelligent Imaging Innovations). Data were binned into three categories based on the range of GFP fluorescence intensities: 0–20 arbitrary units (low; e.g., top right cell in Fig. 3 G), 20–40 arbitrary units (mid; e.g., top left cell in Fig. 3 G), or >40 arbitrary units (high; e.g., top cell in Fig. 3 C). Cell heights were measured using LSM software (Carl Zeiss, Inc.). The lengths of the major and minor cell axes were automatically calculated using the ellipse best-fit module of the Slidebook 4.2 software. 3D volume rendering and fluorescence quantifications (Fig. 5 and S4) were performed with Volocity 4.2 software (Improvision). Data were statistically analyzed using an automated unpaired t-test (http://www.physics.csbsju.edu/stats/t-test.html). Image manipulations were limited to renormalization of linear dynamic ranges and applied equally across the entire image. No gamma corrections were applied.

Microinjections and live-cell imaging

Preimmune and anti-SEPT2 (N5N; 0.5–1 mg/ml needle concentration) sera were dialyzed, concentrated on Microcon 50.000 MW columns (Millipore), mixed with plasmid DNA in 10 mM Hepes, 140 mM KCl, pH 7.4, and injected into the cytoplasm and nuclei of cells with an Eppendorf microinjector. Preimmune and anti-SEPT2 (N5N; 0.5–1 mg/ml needle concentration) sera were dialyzed, concentrated on Microcon 50.000 MW columns (Millipore), mixed with plasmid DNA in 10 mM Hepes, 140 mM KCl, pH 7.4, and injected into the cytoplasm and nuclei of cells with an Eppendorf microinjector. In Fig. 1, MDCK-SEPT2/YFP cells were transfected with plasmids for CFP-tagged p75, LDLR (gifts from E. Rodriguez-Boulan, Weill Medical College of Cornell University, New York, NY), gap (a gift from M. Edidin, The Johns Hopkins University, Baltimore, MD), VSVG or Gallase (gifts from J. Lippincott-Schwartz, NICHD, National Institutes of Health, Bethesda, MD). In Fig. 2, ts045-VSVG-YFP–injected cells were maintained at 41°C for 2 h before shifting the temperature to 32°C for 10 min, and then to 19°C for 30 min in the presence of cycloheximide (50 μg/ml); p75-GFP–injected cells were maintained at 19°C before transferring to media with cycloheximide for 30 min. Subsequently, cells were imaged in cycloheximide (10 μg/ml) containing media.

Cells were imaged in phenol red-free DME supplemented with 25 mM Hepes using the Marianas system (Intelligent Imaging Innovations) equipped with a 175-Watt Xenon light source, a dual galvanometric filter changer with CFP and YFP excitation/emission filters, CoolSNAP HQ interline CCD camera, and a Plan-Apo 100× 1.4 NA oil objective. No-neighbors deconvolution and post-acquisition analysis were performed using Slidebook 4.2. Sum fluorescence intensities for Golgi and plasma membrane regions were measured after image segmentation using the mask and pencil tools of Slidebook. Spatial overlap between tubular–vesicular structures and SEPT2 filaments was determined by the overlap of YFP and CFP fluorescence.

Recombinant proteins and blot overlay assays

Bovine brain tubulin and GST-human kinesin heavy chain motor domain were purchased from Cytoskeleton, Inc. The C-terminal microtubule-binding domain of human MAP4 (aa 654–1090; a gift from I. Macara) and University of Virginia, Charlottesville, VA), and FLAG-tagged MAP1B and MAP8 (gifts from Y. Yang; Stanford University, Stanford, CA) were transfected using the Lipofectamine 2000 reagent (Invitrogen). MDCK cells were transfected with siCONTROL nontargeting siRNA #1 (Dharmacon RNA Technologies), MAP4 (ON-TARGET plus SMART pool; Dharmacon RNA Technologies), and SEPT2 siRNA oligonucleotides as described previously (Spiliotis et al., 2005).
His-SEPT2/6/7 complexes were purified as previously described (Kinoshita et al., 2002; Kremer et al., 2005). In blot overlay assays, brain tubulin was separated by 10% SDS-PAGE and transferred onto nitrocellulose membranes, which were stained with Pancoau S (Sigma-Aldrich). Membranes were scanned, cut into strips, destained, and incubated overnight at 4°C in blocking buffer (10 mM Tris HCl, pH 6.8, 150 mM NaCl, 1 mM DTT, 0.1% Tween 20, 5% nonfat dry milk, and 0.5% BSA). Recombinant proteins and antibodies were diluted in blocking buffer and overlaid on membrane strips. To visualize tubulin-bound proteins, membranes were washed with TBS, 0.1% Tween 20, and incubated in the same buffer containing 2% BSA and antibodies. Blots were subsequently incubated with secondary AlexaFluor 680 and IRdye800-conjugated antibodies and scanned in a Li-COR infrared imager. Quantification of protein bands was performed with the Odyssey Infrared Imaging System (LI-COR Biosciences).

**MDCK cell fractionation on OptiPrep density gradients and Western blotting**

Non-polarized “contact naive” MDCKs were transfected with siCONTROL and SEPT2 siRNAs, and passed twice while being maintained in regular medium for 60 h. Cells (15 × 10⁶) were plated onto collagen-coated 75-mm Transwell filters (Costar) for 24 h, and ball-bearing homogenized in buffer I (25 mM sucrose, 20 mM Hepes KOH, pH 7.1, 90 mM potassium acetate, 2 mM magnesium acetate, 2 mM Pefabloc, and protease inhibitors). Post-nuclear supernatants were adjusted with OptiPrep to 30% iodixanol, overlaid with equal volumes of 20 and 10% iodixanol solutions, and centrifuged at 350,000 × g for 3 h in a VTi 65.1 rotor (Beckman Coulter). Equal volume fractions were collected from the top (p > 1 g/ml) through the bottom (p ~ 1.3 g/ml) of the gradient, and the refractive index (n) of each fraction was measured using a refractometer (Bausch & Lomb). Densities were determined in g/ml [n = (3.433) – 3.599]. For the linear portions of these gradients (fractions 1–23), the densities for the same numbered fractions were equivalent across gradients. Fractions were boiled in SDS sample buffer and analyzed by SDS-PAGE and immunoblotting with antibodies to E-cadherin (rabbit), furin convertase (ABR-Affinity Bio), and SEPT2 fibres with respect to microtubules in un-treated and nocodazole-treated MDCK cells. Fig. S2 shows localization of SEPT2 fibres with respect to microtubules in untreated and nocodazole-treated MDCK cells. Fig. S2 shows a gallery of still images from time-lapse movies of SEPT2-YFP and Golgi-derived vesicular–tubular carriers containing CFP-tagged GalTase, gpi, ts045-VSV-G, p75, and LDL-R. Vesicle fractions were drawn with a syringe and centrifuged at 100,000 g post-18,000 g, pH 7.4, 140 mM KCl, 5 mM EGTA, 1 mM DTT, 2 mM Pefabloc, and protease inhibitors. Post-18,000 g supernatants were incubated in the same buffer containing 2% BSA and antibodies. Blots were incubated in the same buffer containing 2% BSA and antibodies. Blots were incubated in the same buffer containing 2% BSA and antibodies. Blots were incubated in the same buffer containing 2% BSA and antibodies.
