Nuclear lamina alterations occur in physiological aging and in premature aging syndromes. Because aging is also associated with abnormal stem cell homeostasis, we hypothesize that nuclear envelope alterations could have an important impact on stem cell compartments. To evaluate this hypothesis, we examined the number and functional competence of stem cells in Zmpste24-null progeroid mice, which exhibit nuclear lamina defects. We show that Zmpste24 deficiency causes an alteration in the number and proliferative capacity of epidermal stem cells. These changes are associated with an aberrant nuclear architecture of bulge cells and an increase in apoptosis of their supporting cells in the hair bulb region. These alterations are rescued in Zmpste24−/−Lmna−/− mutant mice, which do not manifest progeroid symptoms. We also report that molecular signaling pathways implicated in the regulation of stem cell behavior, such as Wnt and microphthalmia transcription factor, are altered in Zmpste24−/− mice. These findings establish a link between age-related nuclear envelope defects and stem cell dysfunction.

Nuclear envelope defects cause stem cell dysfunction in premature-aging mice

and 19 and α6-integrin, which are markers of epithelial stem cells (Liu et al., 2003; Blanpain and Fuchs, 2006). In all cases, and in agreement with the LRC-based experiments, we observed an increased immunoreactive signal in the bulge region from Zmpste24−/− mice (Fig. 1, B and C; and Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200801096/DC1).

To evaluate the possibility that the accumulation of stem cells observed in Zmpste24−/− mice could be linked to the nuclear architecture alterations previously described in non–stem cells of these mutant mice (Pendas et al., 2002), we examined the nuclear morphology and distribution of heterochromatic and methylated DNA (5-methylcytosine [5mC]) in the epidermis by using confocal microscopy and immunostaining (Fig. 2 A). We observed profound alterations in the nuclear architecture of the Zmpste24−/− hair bulb and interfollicular epithelium cells, which exhibit a clear fusion of heterochromatin clusters (chromocenters).
29 STEM CELL DYSFUNCTION IN PREMATURE-AGING MICE • ESPADA ET AL.

Remarkably, these alterations were rescued in Zmpste24+/H11002/H11002/Lmna+/H11002 normal-aging mice (Fig. 2, A and B).

To try to establish a link between stem cell nuclear alterations and the defective lamin A/C processing characteristic of Zmpste24−/− animals, we analyzed the expression and distribution of pre–lamin A in tail skin hair follicles from Zmpste24+/+ and Zmpste24−/− mice. Immunoblot analysis of lamin A/C in the epidermis of Zmpste24+/+ and Zmpste24−/− animals. Results are representative of three different experiments. Immunolocalization of pre–lamin A in tail skin hair follicles from Zmpste24+/+ and Zmpste24−/− mice. Detailed view of the distribution of lamin A and pre–lamin A in hair follicles from Zmpste24+/+ and Zmpste24−/− animals.

Figure 2. Nuclear architecture alterations in hair follicle stem cells of Zmpste24−/− mice. (A) Distribution of nuclear heterochromatin and 5mC. (B) Chromocenter quantification in hair follicles from the indicated mice. Cells with nuclear aberrations related to apoptosis were excluded from analysis. 100 cells of each region in three animals per genotype were examined. *, P < 0.05. Error bars represent SEM. (C) Immunoblot analysis of lamin A/C in the epidermis of Zmpste24+/+ and Zmpste24−/− animals. Results are representative of three different experiments. (D) Immunolocalization of pre–lamin A in tail skin hair follicles from Zmpste24+/+ and Zmpste24−/− mice. (E) Detailed view of the distribution of lamin A and pre–lamin A in hair follicles from Zmpste24+/+ and Zmpste24−/− animals. Bars: (A) 10 μm; (D) 100 μm; (E) 50 μm.

and associated 5mC in one or two large masses. In contrast, cells from control mice show numerous chromocenters of small size dispersed in the nucleoplasm and frequently associated with the nuclear envelope (Fig. 2 A; Filesi et al., 2005; Shumaker et al., 2006). Similar gross changes in two heterochromatin markers, HP1α and 3mK9H3, were observed in Zmpste24−/− cells (Fig. S2 A, available at http://www.jcb.org/cgi/content/full/jcb.200801096/DC1). Likewise, the determination of chromocenter numbers revealed a significant reduction of heterochromatin clusters in the hair bulb and interfollicular epithelium of Zmpste24−/− animals (Fig. 2 B). Furthermore, Zmpste24−/− bulge cells show a significant depletion of 5mC, a characteristic feature of cell senescence (Fig. 2 A; Howard, 1996). Remarkably, these alterations were rescued in Zmpste24−/− Lmna+/− normal-aging mice (Fig. 2, A and B).
The observed alterations of epidermal stem cell numbers in Zmpste24-/- mice can be initially attributed to a dysfunction in the proliferation or differentiation potential of stem cell reservoirs. To evaluate this question, we first performed clonogenic assays with epidermal cells from newborn and adult Zmpste24-/- mice (Fig. 2C). Likewise, a strong accumulation of pre-lamin A in the nuclear envelope of bulge stem cells was observed in Zmpste24-/- but not in Zmpste24+/- animals (Fig. 2, D and E). According to these results, we conclude that epidermal stem cells from Zmpste24-null mice produce and accumulate pre-lamin A in their nuclear envelope, which, in turn, may contribute to the LRC increase and stem cell alterations observed in these progeroid mice.

The observed alterations of epidermal stem cell numbers in Zmpste24-/- mice can be initially attributed to a dysfunction in the proliferation or differentiation potential of stem cell reservoirs. To evaluate this question, we first performed clonogenic assays with epidermal cells from newborn and adult Zmpste24-/-
and Zmpste24+/− mice (Fig. 3 A). We did not find significant differences in the clonogenic potential of epidermal cells from newborn mice, which agrees with the notion that Zmpste24+/− phenotypic alterations are only detected after several weeks of age (Pendás et al., 2002). In contrast, clear differences were found in the assays performed with epidermal cells from adult mice (Fig. 3 A). Therefore, consistent with the accumulation of LRCs in the bulge region of Zmpste24+/− mice, epidermal cells from these mutant animals generated a higher number of colonies than those from control mice. Interestingly, most colonies formed by Zmpste24+/− epidermal cells were of small size (between 0.5 and 1 mm; 67% in mutant mice vs. 43% in wild type), suggesting a decreased capacity of Zmpste24+/− stem cells to proliferate (Fig. 3 A). The finding that the number and size of colonies obtained from adult Zmpste24+/− Lmna+/− epidermal cells did not differ from those obtained when wild-type epidermal cells were used confirmed the full rescue of the putative stem cell defects when pre–lamin A levels are lowered.

To further evaluate the observed decline in the proliferative potential of Zmpste24+/− stem cells, we investigated the distribution of proliferating cells in the bulge region after treatment with tetradecanoylphorbol 13-acetate (TPA), a tumor promoter that induces the proliferation and differentiation of hair follicle stem cells (Braun et al., 2003). As shown in Fig. 3 B, DNA-replicating cells were absent from the bulge region in both wild-type and Zmpste24−/− untreated mice. After TPA treatment, proliferating cells were detected all along the hair follicle in both wild-type and Zmpste24+/− animals (Fig. 3 B). However, a significant reduction in the number of DNA-replicating cells was observed in the bulge region of Zmpste24+/− animals, indicating the loss of proliferative potential of bulge stem cells from these mutant mice (Fig. 3 B). This proliferative defect was completely rescued in the Zmpste24−/− Lmna+/− normal-aging mice (Fig. 3 B). To determine whether apoptotic changes could also contribute to the reduced proliferative capacity of stem cells from Zmpste24+/− mice, we next analyzed the levels of apoptotic DNA fragmentation in these animals. As shown in Fig. 3 C, we did not find any significant apoptotic changes in the bulge region from Zmpste24+/− mice. However, parallel analysis of the hair bulb region that contains the cells responsible for bulge stem cell maintenance and stimulation revealed a strong increase of DNA fragmentation in Zmpste24+/− mice (Fig. 3 C). Notably, this apoptosis defect was also rescued in Zmpste24−/− Lmna+/− mice (Fig. 3 C). We next investigated the potential induction of apoptosis in the hair follicle after the stimulatory signal provided by TPA. As shown in Fig. 3 C, no significant differences in the number and distribution of apoptotic cells were observed in the hair bulb region of Zmpste24+/− or their wild-type littermates after TPA treatment. We next tested whether stem cells from Zmpste24+/− mice could have changes in their differentiation potential in addition to the observed proliferative deficiencies. However, we failed to observe any difference in the ability of Zmpste24+/− or control epidermal stem cells to differentiate into the four epidermal layers after TPA stimulation (Fig. S2 B). Likewise, no changes were observed in the differentiation potential of epidermal keratinocytes subjected to a Ca2+ shock, a procedure used to assess stem cell multipotency (Fig. S2 C; Flores et al., 2005). Nevertheless, we must emphasize that these assays are only qualitative and of limited sensitivity, and further studies will be necessary to assess the occurrence of putative defects in the differentiation potential of Zmpste24+/− stem cells.

Taking all of these results into account, we can conclude that the accumulation of LRCs in Zmpste24+/− stem cell niches is in part caused by a defect in the proliferation potential of these cells. Moreover, increased apoptosis in the stem cell microenvironment and rapid entry in senescence of a significant proportion of replicating epidermal cells may also contribute to the altered behavior of stem cells in Zmpste24+/− mice. Likewise, the finding that these molecular abnormalities occur in both stem cells and their neighboring and supporting cells suggests that Zmpste24+/− stem cell dysfunction results from the interplay between cell-intrinsic defects and noncell autonomous changes in their microenvironment. These findings also suggest the possible occurrence of defects in signaling pathways involved in the communication between stem cells and their niches in Zmpste24+/− progeroid mice.

Recent studies have provided important information about different signaling pathways involved in the regulation of stem cell functionality (Blanpain and Fuchs, 2006; Clevers, 2006; Jones and Wagers, 2008). Wnt–β-catenin signaling is particularly significant in the context of the observed Zmpste24+/− defects because of its relevance to proper stem cell activity during hair follicle morphogenesis in adult mice (Lo Celso et al., 2004; Clevers, 2006). To investigate putative abnormalities in this regulatory pathway in Zmpste24+/− mice, we first analyzed the expression and intracellular distribution of β-catenin in the epidermis. We found an overall decrease of β-catenin protein levels in Zmpste24+/− as compared with wild-type littermates (Fig. 4 A). Interestingly, no significant differences were found in the distribution of this protein in cells of the interfollicular epithelium or bulge region, whereas the intracellular accumulation of β-catenin in the hair bulb was observed in wild-type animals (Fig. 4 B). We reasoned that the observed cytoplasmic accumulation of β-catenin could represent a signaling-compotent fraction of this protein. To test this hypothesis, we analyzed the expression and distribution of the active form of β-catenin (Act–β-catenin; van Noort et al., 2002). We found high levels of Act–β-catenin in the epidermis of wild-type animals but not in Zmpste24+/− mice (Fig. 4 A). Similarly, a strong intracellular accumulation of Act–β-catenin was found in ~30% of hair follicles in Zmpste24+/− mice (Fig. 4 C). These results agree with the previously reported signaling capacity of β-catenin in this region during hair follicle development but not in the bulge, where Wnt signaling is thought to be constitutively inhibited (Blanpain and Fuchs, 2006). In contrast, <1% of hair follicles from Zmpste24+/− animals contained nuclear β-catenin–positive cells in the hair bulb (Fig. 4 B). Notably, all changes in the expression and distribution patterns of β-catenin observed in the hair follicles of Zmpste24+/− mice were restored in Zmpste24+/− Lmna+/− animals (Fig. 4 A and Fig. S3, A–C; available at http://www.jcb.org/cgi/content/full/jcb.200801096/DC1). In agreement with these observations, we found that the expression of cyclin D1, a direct proliferative target of the Wnt–β-catenin pathway (Tetsu and McCormick, 1999), was significantly reduced.
Pam212 cells treated with specific siRNA directed to Zmpste24 mRNA as compared with cells treated with control scrambled siRNA (Fig. 4E). Therefore, according to these results, we can conclude that Wnt signaling is down-regulated by Zmpste24 depletion and can be altered in the stem cell–supporting epidermal hair bulb compartment of Zmpste24/H11002/H11002 mice. These findings are also of interest in the context of a recent study describing hyperactive Wnt signaling in a mouse model of accelerated aging caused by a mutation of Klotho (Liu et al., 2007). Despite the apparent divergence between our study and that of Liu et al. (2007), it must be emphasized that Klotho mice present hyperactive Wnt and a reduced number of bulge stem cells, whereas we have observed reduced Wnt signaling associated with stem cell accumulation in Zmpste24/−/− animals, thus establishing a putative connection between both models.

Figure 4. Zmpste24 deficiency disrupts signaling pathways implicated in stem cell regulation in the hair follicle. (A) Immunoblot analysis of levels of β-catenin, active β-catenin, and Mitf in the epidermis of the indicated mice. β-Actin was analyzed as a loading control. Results are representative of three different animals per genotype. (B and C) Distribution of β-catenin and Act–β-catenin in tail skin hair follicles from Zmpste24+/+ and Zmpste24/−/− mice. (B) Boxed areas are magnified in the bottom panels. (D) Quantification of cyclin D1 and Hoxc13 mRNA by quantitative RT-PCR. Data were normalized to actin expression. Results are representative of three experiments. (middle and right) Normalized luciferase/renilla activities of reporter vectors transiently transfected in Pam212 cells containing either multimerized promoter sequences recognized by β-catenin–leff/tcf complexes (pTOPFLASH; TOP), the same mutated sequences (pFOPFLASH; FOP), or the human cyclin D1 promoter. Assays were performed in triplicate. (F) Distribution of Mitf in the skin from Zmpste24+/+ and Zmpste24/−/− mice. (G) Quantification of mRNA expression by quantitative RT-PCR of dopachrome tautomerase and Tyrp1. **, P < 0.01. Error bars represent SEM. Bars: (B) 100 μm; (C) 20 μm; (F) 50 μm.

in the epidermis of Zmpste24/−/− animals (Fig. 4D). Likewise, we found that the activation of Akt and mTOR, two central transducers of the PI3K–Akt signaling pathway that modulate Wnt signaling in stem cells (Tian et al., 2005), was also repressed in the hair follicle of Zmpste24-null mice (Fig. S3D).

To further investigate the causal role of pre–lamin A accumulation in the Wnt signaling dysfunction observed in Zmpste24/−/− mice, we performed a series of gene reporter assays in Pam212 mouse keratinocytes. To this end, the transcriptional activity of constructs containing multimerized wild-type and mutated β-catenin/Lef1-binding sites or the mouse cyclin D1 gene promoter fused to the luciferase reporter gene was analyzed in these cells after reducing their Zmpste24 levels by RNAi (Fig. 4E). As can be seen in Fig. 4E, both β-catenin–dependent and cyclin D1 promoter transcription were efficiently inhibited in Pam212 cells treated with specific siRNA directed to Zmpste24 mRNA as compared with cells treated with control scrambled siRNA (Fig. 4E). Therefore, according to these results, we can conclude that Wnt signaling is down-regulated by Zmpste24 depletion and can be altered in the stem cell–supporting epidermal hair bulb compartment of Zmpste24/−/− mice. These findings are also of interest in the context of a recent study describing hyperactive Wnt signaling in a mouse model of accelerated aging caused by a mutation of Klotho (Liu et al., 2007). Despite the apparent divergence between our study and that of Liu et al. (2007), it must be emphasized that Klotho mice present hyperactive Wnt and a reduced number of bulge stem cells, whereas we have observed reduced Wnt signaling associated with stem cell accumulation in Zmpste24/−/− animals, thus establishing a putative connection between both models.
Finally, we tested whether signaling pathways involved in the proliferation and differentiation of other stem cells present in the bulge yet distinct from epithelial stem cells could also be altered in Zmpste24 null mice. For this purpose, we examined the protein levels of the microphthalmia transcription factor (Mitf), a master regulator of melanocyte stem cells that interacts with β-catenin to determine target gene expression (Nishimura et al., 2002; Schepsy et al., 2006). As seen in Fig. 4 A, very low levels of this transcription factor are present in the epidermis of Zmpste24 null mice when compared with controls. Levels of Mitf expression were recovered in Zmpste24 null mice (Fig. 4 A).

Immunofluorescence analysis also revealed the strong reduction of Mitf levels in hair follicles from Zmpste24 null animals (Fig. 4 F). To further examine the loss of Mitf signaling in Zmpste24 null mice, we analyzed the expression of dopachrome tautomerase and tyrosinase-related protein 1 (Tyrp1), which are central effectors of Mitf in the bulge region (Nishimura et al., 2002). As shown in Fig. 4 G, we found that both Mitf effectors were severely down-regulated in Zmpste24 null animals. From these results, we conclude that defective signaling of molecular circuits implicated in the functional regulation of epidermal (Wnt) or melanocyte (Mitf) stem cell activity in the skin occurs in Zmpste24-deficient mice. Remarkably, levels of the regulatory homeoprotein Hoxc13, which plays essential roles in hair follicle differentiation (Goddwin and Capecci, 1998), were maintained in Zmpste24 null mice (Fig. 4 D), ruling out the occurrence of a general defect in this compartment that could affect all signaling pathways.

In summary, the results presented in this study are consistent with the proposal that the defects in nuclear architecture originally associated with progeroid syndromes in both mice and human have a strong impact on stem cells. By using mice deficient in specific components of the lamin A/Zmpste24 system, we have found that their stem cells accumulate in the hair follicle mainly as a result of defects in their proliferative potential. These deficiencies are linked to profound chromatin abnormalities as well as to the subsequent loss of signaling pathways, such as Wnt and Mitf, which play important roles in the regulation of stem cell number, fate, and function. These findings, together with the recent observation that nuclear envelope abnormalities could also be a central cause of normal aging (Haithcock et al., 2005; Scafidi and Misteli, 2006), emphasize the relevance of progeria models to gain new insights into the connections between stem cell dysfunction and aging. These results also provide experimental support to the proposal that adult stem cell abnormalities may also influence the development of other laminopathies caused by defects in the nuclear envelope (Hutchison and Worman, 2004; Gotzmann and Foisner, 2006). In this regard, it is also interesting that Lmna is one of the genes markedly down-regulated in aged hematopoietic stem cells (Chambers et al., 2007), reinforcing the proposed importance of nuclear envelope alterations for stem cell dysregulation during aging. Finally, the observation that stem cell defects in Zmpste24 null mice are rescued in Zmpste24 null mice provides evidence for the causal relationship between nuclear lamina defects and stem cell dysfunction and opens the possibility of exploring new therapeutic approaches for human progeroid syndromes.

Materials and methods

Animals
Zmpste24+/− and Zmpste24−/− Lmna+/− mice were generated and genotyped as described previously (Pendás et al., 2002; Varela et al., 2005). To induce LK supplementation, interfollicular epithelium hyperplasia, and anagen entry, tail skin from a group of six 75-d-old mice per genotype in the telogen (resting) phase of the hair cycle was topically treated every 48 h with TPA (20 nmol in acetone) for a total of three doses. Six control mice of each genotype were treated with acetone alone. 24 h after the last TPA treatment, mice were killed, and the tail skin was analyzed. Animal experimentation was performed in accordance with the guidelines of the Universidad de Oviedo.

Cultured keratinocytes, RNAi, and gene reporter assays
Pam212 is an immortalized and spontaneously transformed cell line from a BALB/c primary keratinocyte culture. Cells were grown in DMEM containing 10% (vol/vol) FCS, 50 μU/ml penicillin, 50 μg/ml streptomycin, and 1% (vol/vol) of 0.2 M glutamine (all were obtained from Invitrogen). For Zmpste24 RNAi, early subconfluent Pam212 cells were repeatedly transfected for 72 h with 100 nM of a validated siRNA duplex targeting Zmpste24 mRNA (Qiagen). Transfections were performed every 24 h using Oligofectamine (Invitrogen) in OptiMEM (Invitrogen) culture medium according to the manufacturer’s instructions. For gene reporter assays, late subconfluent cells were transfected in duplicate in T-24 plates with 200 ng of either pTOPFLASH or pFOPFLASH containing mutated wild-type and mutated β-catenin/Lef1 binding sites, respectively (a gift from H. Clevers, Netherlands Institute for Developmental Biology, Utrecht, Netherlands), or the mouse cyclin D1 promoter (a gift from A. Muñoz, Instituto de Investigaciones Biomedicas, Madrid, Spain) fused to the luciferase reporter gene. 600 ng of activator plasmid was added in each case as indicated. Activator plasmids included pCI-Lef1 (provided by H. Clevers) and pClNmut-Lef1 encoding a metabolically stabilized β-catenin S33Y (a gift from A. Ben-Ze’ev, Weizmann Institute of Science, Rehovot, Israel). Transfections were performed with Lipofectamine reagent (Invitrogen). DNA quantities were normalized with empty pcDNA3. Luciferase and Renilla activities were measured 24 h after transfection using the Dual Luciferase Reporter kit (Promega).

BrdU labeling of cells
BrdU LRCs were detected as previously described (Braun et al., 2003). In brief, mice were injected with 50 mg/kg body weight BrdU (Sigma-Aldrich) diluted in PBS. Each animal received a daily injection beginning at day 4 of life for a total of 5 d. After the labeling period, mice were allowed to grow for 60 d before the initiation of any treatment. Cells retaining the label at the end of the treatment were identified as LRCs. For short-term labeling, mice were treated daily beginning 4 d before being killed.

Histology and preparation of whole mounts
Tissue samples were harvested from mice, fixed overnight in neutral-buffered formalin, dehydrated through graded alcohols and xylene, and embedded in paraffin. Whole mounts of mouse tail epidermis were prepared as described previously (Braun et al., 2003). In brief, after mice were killed and tails were clipped, skin was peeled from the tails and incubated in 3 mM EDTA in PBS at 37°C for 4 h. Using forceps, intact sheets of epidermis were separated from the dermis and fixed in neutral-buffered formalin for 2 h at room temperature. Fixed epidermal sheets were maintained in PBS containing 0.2% sodium azide at 4°C before labeling.

Immunological methods
For immunofluorescence analysis of paraffin sections, slides were deparaffinized and rehydrated. When required, antigen retrieval was performed at 95°C for 40 min in 10 mM citrate containing 0.5% Triton X-100. Slides were washed in water, blocked in 5% BSA (Sigma-Aldrich) for 10 min, incubated with primary antibodies for 1 h at 37°C, washed in PBS, incubated for 40 min with secondary antibodies, thoroughly washed in water, and mounted in Vectashield (Vector Laboratories) containing DAPI for nuclear counterstaining. For immunofluorescence of tail skin whole mounts, epidermal sheets were blocked and permeabilized in PBS containing 0.5% gelatin and 0.5% Triton X-100 (PGT) for 30 min and incubated with primary antibodies diluted in PGT overnight at 37°C. Samples were washed in PGT for 1 h, incubated for 2 h with secondary antibodies, washed in PGT, cleared in water, and mounted in Vectashield. Protein extracts for immunoblot analysis were obtained in NT buffer (50 mM Tris-HCl, pH 7.4), 100 mM EDTA.
