IGFBP-5 regulates muscle cell differentiation by binding to IGF-II and switching on the IGF-II auto-regulation loop.

**Introduction**

Myogenesis is a highly ordered and balanced process, which includes myoblast proliferation, cell cycle withdrawal, differentiation, and cell fusion (Buckingham et al., 2003). This process is regulated by a variety of hormones and growth factors. Insulin-like growth factors (IGFs), including IGF-I and IGF-II, play critical roles in skeletal muscle differentiation and growth, as well as adult muscle regeneration and hypertrophy (Musaro et al., 2001, 2004). Mice deficient in IGF ligand or IGF-I receptor exhibit muscle hypoplasia and die shortly after birth due to impaired muscle mass to inflate their lungs (Liu et al., 1993; Powell-Braxton et al., 1993). Transgenic mice with overexpression of IGF-I in muscle have larger muscle fibers and enhanced muscle strength during aging (Coleman et al., 1995; Barton-Davis et al., 1998; Barton et al., 2002; Kaspar et al., 2003). In cultured muscle cells, IGF-II levels increase dramatically during myogenesis. IGF-II antisense oligonucleotides can abolish differentiation (Florini et al., 1991, 1993), and IGF-II overexpression accelerates myoblast differentiation (Stewart et al., 1996).

Although most growth factors stimulate myoblast proliferation and inhibit myogenic differentiation, IGFs are unique in that they not only stimulate myoblast proliferation but also promote myogenic differentiation, two mutually exclusive processes (Florini et al., 1996). These actions are mediated through the IGF-I receptor (IGF-IR), a transmembrane tyrosine kinase, and activation of the IGF-IR initiates downstream signaling cascades including the phosphatidylinositol 3-kinase (PI3K)-Akt pathway. Earlier studies have shown that there is a temporal separation between these two responses to IGFs: IGF treatment causes a proliferative response in the first 24–36 h, and this is followed by subsequent increase in myogenic differentiation. The increase in differentiation is not secondary to increased cell number after IGF treatment (Florini et al., 1996). Rosenthal and Cheng (1995) have reported a biphasic effect of IGF-I on pRb, a regulator of cell cycle progression that is present in the hyperphosphorylated state during cell proliferation and hypophosphorylated state during differentiation. They found that IGF treatment resulted in persistent Rb hyperphosphorylation for over 24 h before hypophosphorylation became the dominant form. Several laboratories have shown that activation of PI3K, Akt, and FoxO promotes myogenic differentiation and survival (Engert et al., 1996; Kaliman...
IGFBPs are a family of secreted proteins that specifically bind cellular environment are bound to IGF binding proteins (IGFBPs). The ligand (IGF-II) can elicit opposite biological responses. Puzzling how the activation of the same IGF-IR by the same mechanisms underlying IGF actions in myogenesis, it remains unclear why the knockdown of IGFBP-5 impairs myogenic differentiation and reduces IGF-IR-mediated signaling activity. Further mechanistic analyses suggest that IGFBP-5 promotes muscle cell differentiation by binding to IGF-II and enhances the IGF-II autocrine regulatory loop.

**Results**

Induction of IGFBP-5 precedes that of IGF-II during myogenesis

C2C12 myoblasts undergo terminal differentiation after switching to horse serum containing differentiation medium (DM). As shown in Fig. 1A, at 24 h after the induction of differentiation, the expression of IGFBP-5 mRNA showed an approximate sevenfold increase over the 0 h control (P < 0.05). There was a further increase (approximately fivefold) at 48 h. Thereafter, the IGFBP-5 mRNA levels decreased considerably, but remained higher than 0 h. In comparison, while the absolute IGF-II mRNA level (copy number/μl) remained extremely low, the relative levels of IGF-II mRNA increased dramatically at 48 h (51-fold over 24 h, P < 0.05). There was a further approximate fourfold...
increase at 72 h and an additional approximate twofold increase at 96 h. RT-PCR analysis indicated that there are no significant changes in the mRNA levels of IGF-1R, IGFBP-2, and IGFBP-4 (unpublished data; also see Fig. 5 A). These results suggest that although both IGF-II and IGFBP-5 expression are induced during myogenic differentiation, the induction of IGFBP-5 expression precedes that of IGF-II.

**Induction of IGFBP-5 expression is required for myogenic differentiation**

To determine the role of endogenous IGFBP-5, pSUPER-BP5, a plasmid that generates siRNA specifically targeting IGFBP-5 mRNA, was transfected to cultured C2C12 cells. The effect in silencing the IGFBP-5 gene was examined by measuring changes in IGFBP-5 mRNA, as well as changes in IGFBP-5 protein levels. Introducing pSUPER-BP5 into these cells resulted in a marked reduction of IGFBP-5 mRNA levels, whereas the empty pSUPER plasmid had no such effect (Fig. 2 A). Ligand blot analysis of the conditioned media revealed a similar decrease in IGFBP-5 protein levels (Fig. 2 B). The specificity of IGFBP-5 siRNA was confirmed by the unchanged levels of IGFBP-4 mRNA and GAPDH mRNA (Fig. 2 A). Quantification of three independent experiments showed that IGFBP-5 siRNA caused a 72.8% decrease (P < 0.05) in IGFBP-5 mRNA levels and a 71.2% decrease (P < 0.05) in protein levels.

When switched to DM, the empty control vector–transfected myoblasts formed morphologically distinctive multinucleated myotubes, while pSUPER-BP5–transfected myoblasts remained as individual mononucleated cells (Fig. 2 C). We examined the expression of MHC by immunostaining and Western blot. Both assays showed a dramatic decrease in MHC expression in the pSUPER-BP5–transfected cells (Fig. 2, D and E). Quantification of Western blot data from four independent experiments showed that the MHC levels were decreased by 84.4% (P < 0.05). To rule out the possibility of any nonspecific interferon responses associated with siRNA, a pSUPER construct expressing siRNA with a sequence unrelated to IGFBP-5 was engineered and introduced to C2C12 cells. This construct did not affect differentiation or MHC expression (Fig. 2, C–E). Together, these results indicated that knockdown of IGFBP-5 impairs myogenic differentiation in C2C12 cells.

**Knockdown of IGFBP-5 suppresses myogenin expression, but expression of Myogenin cannot “rescue” the myogenic defects caused by IGFBP-5 knockdown**

The muscle-specific myogenic regulatory factors, including MyoD, Myf5, MRF4, and Myogenin regulate myoblast specification and differentiation through their ability to activate muscle specific structural genes, such as MHC (Perry and Rudnick, 2000). We examined whether the expression of some of these critical myogenic transcription factors is altered by IGFBP-5 knockdown. There was little difference of MyoD levels through the time course of differentiation (Fig. 3 A). Myogenin was not detectable in undifferentiated myoblast cells or within the first 24 h after DM was added (Fig. 3 B). At 48 h, Myogenin was...
genin and pSUPER-BP5 were indistinguishable from those transfected with pSUPER-BP5 alone, i.e., they did not form myotubes and had minimal MHC expression when grown in DM. To confirm that the myogenin transgene is functional in this particular experimental setting, the transcriptional activity of Myc-Myogenin was examined. Myogenin forms heterodimers with other ubiquitous basic helix-loop-helix transcription factors and binds to the cis-control elements termed E-boxes often found in the promoters of muscle-specific genes (Sabourin and Rudnicki, 2000; Buckingham, 2001). 4RTK is a reporter construct that contains the firefly luciferase gene driven by a minimal thymidine kinase (TK) promoter linked with four copies of the E-box derived from the mouse muscle creatine kinase promoter. As shown in Fig. 4 C, when cotransfected with 4RTK, the Myc-Myogenin caused a sixfold increase in luciferase activity. Furthermore, when transfected to C2C12 cells, Myogenin significantly increased differentiation at 24 and 36 h after the induction of differentiation (Fig. 4 D), suggesting that overexpression of Myogenin is capable of promoting differentiation. Together, these data indicate that while knockdown of IGFBP-5 reduces myogenin gene expression, myogenin alone is insufficient to promote myogenic differentiation in the absence of IGFBP-5. Knockdown of IGFBP-5 suppresses IGF-II gene expression and exogenous IGF-II "rescues" the myogenic defects caused by IGFBP-5 knockdown

It has been reported that autocrine IGF-II is a critical regulator of myogenesis (Wilson et al., 2004). We therefore examined the impact of IGFBP-5 knockdown on IGF-II expression. No IGF-II mRNA was detected by RT-PCR in the control undifferentiated C2C12 myoblast cells (Fig. 5 A). 24 h after the addition of DM, the IGF-II mRNA levels were appreciated and showed further increases at 48 h and thereafter. IGF-II mRNA expression was undetectable at 24 h and was markedly lower at 48 h in the pSUPER-BP5–transfected cells. This effect appears to be specific

easily detectable and its levels increased dramatically at 72 and 96 h in the control group. At 48 and 72 h, Myogenin was not detected in pSUPER-BP5–transfected cells (Fig. 3 B). Its levels were markedly lower even at 96 h. Northern blot analysis revealed similar decreases in myogenin mRNA levels (Fig. 3 C).

To determine whether myogenin mediates the myogenic action of IGFBP-5, we cotransfected C2C12 myoblasts with pSUPER-BP5 and a Myogenin expression plasmid. Western blot analysis verified the successful expression of the Myc-tagged Myogenin. Knockdown of IGFBP-5 suppressed the endogenous Myogenin and modestly decreased the levels of the transgene (Fig. 4 A). As shown in Fig. 4 B, cells cotransfected with Myo-
to the IGF-II gene, as knockdown of IGFBP-5 did not reduce the mRNA levels of other members of the IGF signaling pathway expressed in these cells, including IGF-I, IGF-IR, and IGFBP-2 and -4 (Fig. 5 A). The effect on IGF-II gene expression was further examined by qRT-PCR. IGF-II mRNA levels were significantly lower in IGFBP-5 knocked down cells at 24, 48, and 72 h after the induction of differentiation (Fig. 5 B). Knockdown of IGFBP-5 markedly decreased phospho-Akt levels, whereas the levels of total Akt remained comparable to those of the control. When quantified and expressed as the ratio of phospho-Akt/total Akt, the levels in the IGFBP-5–deficient group showed a 94% reduction (Fig. 5 C).

Because knockdown of IGFBP-5 suppresses IGF-II expression and reduces the IGF signaling activity, we tested whether IGFBP-5 affects myogenesis via IGF-II. As shown in Fig. 6 A, while pSUPER-BP-5 transfected cells remained as mononucleated myoblasts, addition of exogenous IGF-II not only increased myotube formation in the control group, it also reversed the myogenic defects caused by IGFBP-5 knockdown. IGF-I, which signals through the same IGF-IR, had a similar effect. Western blot
If IGFBP-5 indeed promotes myogenesis through the IGF-IR-PI3K-Akt signaling pathway, then activation of Akt should also "rescue" IGFBP-5 knockdown-induced differentiation defects. To test this idea, myrAkt, a constitutively active form of Akt, was introduced to the cells. As shown in Fig. 6 D, C2C12 cells cotransfected with pSUPER-BP5 and a myrAkt-expressing analysis indicated that knockdown of IGFBP-5 suppressed MHC and Myogenin expression and addition of IGF-II restored their expression (Fig. 6 B). This action of exogenous IGF-II is likely mediated by the IGF-IR and Akt signaling pathway because knockdown of IGFBP-5 reduced phospho-Akt levels and IGF-II increased phospho-Akt levels in differentiating cells (Fig. 6 C).

Figure 7. IGF-II up-regulates its own gene expression through the PI3K-Akt signaling pathway. (A) Wild-type C2C12 cells were switched to SFM supplemented with or without 300 ng/ml IGF-II. IGF-II mRNA levels were measured by qRT-PCR and normalized by cyclophilin mRNA levels. Data shown represent means ± SE of two independent experiments. *, P < 0.05 compared with the control group at the same time point. (B) Wild-type C2C12 cells were switched to DM (containing 0.5% horse serum) supplemented with or without 300 ng/ml IGF-II. 24 and 36 h later, cells were lysed and subjected to Western blot analysis. (C) Cells transfected with the empty pCS2 [open box] or pCS2+myr-Akt plasmid [closed box] were switched to DM. IGF-II mRNA levels were measured by qRT-PCR and normalized. The results were expressed as relative value to those of the empty vector transfected cells at 0 h. Data shown are means ± SE of three independent experiments. *, P < 0.05; **, P < 0.01 compared with the control group at the same time point. (D) C2C12 cells transfected with the empty pCS2+ or pCS2+myr-Akt plasmid were switched to the DM. Cells were lysed at the indicated time and subjected to Western blot analysis. (E) Overexpression of Myogenin does not restore the reduced IGF-II expression in IGFBP-5 knocked down cells. Cells transfected with pSUPER + pCS2, pSUPER + Myc-Myogenin, pSUPER-BP5 + pCS2, and pSUPER-BP5 + Myc-Myogenin were induced to differentiate for 4 d. RNA samples were prepared and subjected to RT-PCR analysis.
IGF-II up-regulates its own gene expression via the PI3K-Akt signaling pathway

Although it has been shown that autocrine IGF-II production increases dramatically during muscle differentiation, the regulatory mechanisms of IGF-II gene expression is not well understood. Given the fact that IGF-II gene expression is continuously and dramatically elevated during myogenesis (see Fig. 1), we speculated that IGF-II might up-regulate its own gene expression through a positive auto-regulatory loop. Two independent approaches, adding exogenous IGF-II and overexpressing myrAkt, were taken to address this issue. As shown in Fig. 7 A, addition of IGF-II to wild-type C2C12 cells resulted in a significant increase in IGF-II mRNA levels. Likewise, expression of myrAkt significantly increased IGF-II mRNA levels (Fig. 7 C). These results suggest that IGF-II up-regulates its own gene expression through the PI3K and Akt signaling pathway.

In addition to IGF-II, Myogenin expression was also increased by exogenous IGF-II or myrAkt expression (Fig. 7, B and D). These data are consistent with previous reports (Florini et al., 1993; Xu and Wu, 2000). However, expression of Myogenin did not restore the reduced IGF-II expression caused by IGFBP-5 knockdown cells (Fig. 7 E). Although the increased Myogenin plays a role in myogenesis, it does not appear to play any direct role in the expression of the IGF-II gene during myogenesis.

Endogenous IGFBP-5 is not localized in the nucleus, and forced nuclear expression of the IGFBP-5 transactivation domain does not increase IGF-II expression

Recent studies have shown that IGFBP-5 is not only secreted, but can also enter the nucleus in certain cell types and that IGFBP-5 contains a functional transactivation domain in its conserved N-domain (Firth and Baxter, 2002; Xu et al., 2004; Zhao et al., 2006). We wondered whether IGFBP-5 could exert a direct effect on IGF-II transcription in the nucleus. To test this idea, immunocytochemical experiments were performed to determine whether endogenous IGFBP-5 is present in the nucleus in differentiating C2C12 cells. Confocal microscopy analysis showed that endogenous IGFBP-5 signal was detected in the Golgi apparatus, in the shape of a crescent moon outside of the nucleus (Fig. 8 A, a–d). This is consistent with the fact that IGFBP-5 is secreted from these cells. To show that the IGFBP-5 antibody could detect nuclear IGFBP-5 if present, we generated a plasmid that expresses a nonsecreted form of IGFBP-5 (with the signal peptide deleted) with an EGF tag at its N terminus, and introduced it into cells by transient transfection. The nonsecreted EGFP-mIGFBP-5 was clearly localized in the nucleus as indicated by the overlap of GFP signal and IGFBP-5 immunoreactivity with DAPI signal (Fig. 8 A, e–h). These results indicate endogenous IGFBP-5 is not localized in the nucleus in myoblasts. Next, we transfected C2C12 cells with an IGFBP-5 construct that contains its functional transactivation domain (Xu et al., 2004) and examined its impact on the IGF-II gene expression. As shown in Fig. 8 B, no significant increase was detected in IGF-II mRNA expression levels in the control or IGFBP-5-transfected cells, although the IGFBP-5 fusion protein was highly expressed (Fig. 8 C). In comparison, myrAkt overexpression significantly increased IGF-II mRNA levels (Fig. 8 B). Together, these results suggest that endogenous IGFBP-5 is not localized in the nucleus and forced nuclear expression of the IGFBP-5 transactivation domain does not increase IGF-II expression in differentiating myoblast cells.

IGFBP-5 promotes myogenic differentiation by switching on the IGF-II auto-regulatory loop

How does IGFBP-5 act to increase IGF-II gene expression and to promote myogenesis? IGFBP-5 has been shown to be located on the cell surface and/or extracellular matrix in fibroblasts and muscle cells (Clemmons, 2001). Because IGF-II stimulates its own gene expression through a positive auto-regulatory loop, we hypothesized that cell surface–associated IGFBP-5 up-regulates IGF-II gene expression and promotes myogenesis by binding to IGF-II and enhances its interaction with the IGF-IR, thereafter...
amplifying IGF signaling activity during myogenesis. To test this hypothesis, immunocytochemical staining was performed. As shown in Fig. 9 A, IGFBP-5 signal was clearly observed on the surface of cells that were fixed in a buffer containing no detergent and therefore with the integrity of the plasma membrane intact (panel a). When the plasma membrane was permealized, however, no such signal was observed, even though intracellular IGFBP-5 was clearly visible (Fig. 9 A, panel b). We further demonstrated that intact IGFBP-5 is present on the surface of differentiating myoblasts and is capable of IGF binding by treating C2C12 cells with a high salt buffer to strip off membrane/ECM bound IGFBP-5. The released IGFBP-5 was detected by ligand blot. [C] C2C12 cells were switched to serum-free medium containing 300 ng/ml IGF-II or Des(1-6)IGF-II. 36 h later, the cells were subjected to MHC immunostaining and DAPI staining and the differentiation index determined as described in Materials and methods. Data are means ± SE of three independent experiments with duplicates. Group *, #, and • are significantly different from each other at P < 0.05. [D] Cells transfected with pSUPER or pSUPER-BP5 were switched to DM (containing 0.5% horse serum) without or with 50 ng/ml IGF-II, 50 ng/ml IGF-II + 210 ng/ml wild-type IGFBP-5, 210 ng/ml wild-type IGFBP-5, 50 ng/ml IGFBP-5 + 210 ng/ml LBD-IGFBP-5, 210 ng/ml LBD-IGFBP-5, or 150 ng/ml IGF-II for 4 d. MHC levels were measured by Western immunoblot and quantified by densitometry. Values are expressed as relative to the IGFBP-5 siRNA group. Data are means ± SE of 3–4 independent experiments. Group * is significantly different from group # at P < 0.05.

The IGFBP-5 and IGF-II genes are similarly induced in primary myoblasts and IGFBP-5 knockdown inhibits primary cell differentiation

To establish the physiological relevance of the above observations, we examined the IGF-II and IGFBP-5 mRNA expression patterns in primary skeletal myoblasts prepared from neonatal mice. As shown in Fig. 10 A, 24 h after the initiation of differentiation, the expression of IGFBP-5 mRNA showed a 2.9-fold increase over the 12 h control (P < 0.05). Thereafter, the IGFBP-5 mRNA levels returned to the basal levels. In comparison, the IGF-II mRNA level remained unchanged at this early stage of differentiation. The IGF-II mRNA levels increased significantly at 36 h (4.6-fold over 12 h, P < 0.05) and remained significantly high at 48 h (3.6-fold, P < 0.05). Therefore, the overall patterns of IGF-II and IGFBP-5 induction and their temporal relationship are similar in these primary cells, although the magnitude of inductions is lower. To examine the role of IGFBP-5, primary skeletal muscle cells were transfected with pSUPER or pSUPER-BP5. When switched to DM, the vector transfected myoblasts formed morphologically distinctive multinucleated myotubes and expressed MHC (Fig. 10 B). In comparison, most pSUPER-BP5–transfected myoblasts had fewer MHC-positive cells. The differentiation index in the pSUPER-BP5–transfected group is 37.5% (Fig. 10 C), which is significantly lower than
that of the control group (58.4%, P < 0.05). These findings suggest that the induction of IGFBP-5 occurs earlier than that of IGF-II and that IGFBP-5 promotes myogenic differentiation in primary skeletal muscle cells.

**Discussion**

In this study, we have explored the role(s) of endogenous IGFBP-5 in modulating the action of autocrine IGF-II in promoting myogenic differentiation. We show that knockdown of IGFBP-5 impairs myogenic differentiation. Addition of IGF-II “rescues” IGFBP-5 knockdown-induced myogenic defects, while Des(1-6)IGF-II, an IGF-II analogue with greatly reduced binding affinity for IGFBP, is significantly less effective. These data strongly argue that the endogenously secreted IGFBP-5 is a differentiation-promoting factor in skeletal muscle cells. This conclusion makes physiological sense in light of the highly induced IGFBP-5 expression before an appreciable increase in IGF-II production during early myogenesis. It is also in agreement with several previous studies. It has been reported that NFB4 cells, a mutant muscle cell line derived from C2C12 cells that are deficient in IGFBP-5 and IGF-II, do not undergo differentiation under the conditions in which C2C12 cells differentiate (Sarbassov et al., 1995). When added in an appropriate ratio to IGF-I, IGFBP-5 stimulates IGF-induced myoblast differentiation in rat muscle cells (Ewton et al., 1998). Recent loss-of-function studies in other cell types also suggest that IGFBP-5 promote bone, neuronal and epithelial cell differentiation (Yin et al., 2004; Tanno et al., 2005; Kiepe et al., 2006; Lochrie et al., 2006). More importantly, the IGFBP-5 and IGF-II genes exhibit similar expression patterns.
patterns in primary skeletal muscle cells and knockdown of IGFBP-5 inhibits myogenic differentiation in primary cells. These findings suggest that IGFBP-5 promotes muscle cell differentiation and this finding is of physiological relevance.

Our finding, however, contradicts the view that IGFBP-5 is a negative factor of myogenesis. Several previous studies in C2 myoblasts have shown that stably overexpressing IGFBP-5 under a constitutive promoter impairs myogenic differentiation, presumably by binding to and sequestering IGF-II from its binding to the IGF-IR (James et al., 1996; Mukherjee et al., 2007). The different findings on the precise role IGFBP-5 in myogenesis could be due to different experimental approaches used. In the present study, we explored the role of endogenous IGFBP-5 through a loss-of-function approach followed by “rescuing” using proteins, whereas previous studies primarily relied on overexpression approaches. The different results may also be due to different cell lines used. Previous studies were conducted experiments with C2 cells (James et al., 1996; Cobb et al., 2004; Mukherjee et al., 2007). Instead, we used the C2C12 cell line, which is subcloned from the parent C2 cell line by selection for the ability to differentiate rapidly and produce extensive contracting myotubes (Silberstein et al., 1986). Moreover, we obtained similar results in primary skeletal muscle cells, strongly supporting the physiological relevance of our findings.

IGFBP-5, Myogenin, and IGF-II are all induced during differentiation (Rotwein et al., 1995; Bayol et al., 2000). The expression of IGFBP-5 correlates well with the expression of Myogenin (Bergstrom and Tapscott, 2001). Myogenin, IGF-II, and IGFBP-5 were undetectable in the mutant NF4B4 cells, which cannot go through differentiation (Sarbassov et al., 1995). In cultured muscle cells, endogenously secreted IGFBP-II stimulates the IGF-IR, PI3K, and Akt to induce the expression of Myogenin (Wilson et al., 2004). The functional relationship between IGFBP-5, Myogenin, and IGF-II is not well understood. In this study, we found that IGFBP-5 knockdown caused marked reduction in both Myogenin and IGF-II expression, but had little effect on MyoD expression. Forced expression of functional Myogenin, however, failed to rescue the differentiation defects caused by IGFBP-5 knockdown, although it increased the differentiation index in the wild-type cells. It is noted that IGFBP-5 siRNA not only markedly decreased endogenous Myogenin expression levels but also caused a modest reduction in the expression levels of the Myogenin transgene. Importantly, forced expression of Myogenin did not cause significant changes in either IGF-II or IGFBP-5 mRNA levels. This suggests that while IGFBP-5 is induced in early stages of myogenesis, before the differentiation index in the wild-type cells. It is noted that IGFBP-5 regulates Myogenin expression, Myogenin itself is not sufficient to induce myogenic differentiation in the absence of IGFBP-5 and/or IGF-II. Other factors must also be involved in the effect of IGFBP-5 on myogenesis. Future studies are needed to identify these factors.

One of the intriguing findings made in this study is that IGFBP-5 knockdown suppresses IGF-II expression. IGFBP-5 knockdown had little effect on the IGF-I and IGF-IR mRNA levels. Knockdown of IGFBP-5 did not affect the levels of other IGFBPs synthesized by C2C12 either. The specificity of this siRNA construct has been verified using a siRNA resistant form of IGFBP-5 in U2OS cells (Yin et al., 2004). In addition, the suppressed IGF-II expression was reversed by adding IGFBP-5 together with low concentrations of IGF-II or by a high concentration of IGF-II. Expression of myrAkt also restores IGF-II expression levels. We also ruled out nonspecific interferon responses using another pSUPER construct expressing siRNA with a sequence unrelated to IGFBP-5. Our data showed that myrAkt overexpression significantly increased IGF-II gene expression 12 h after differentiation was induced. It is possible that Akt also regulates IGF-II gene expression during the early phase of myogenesis. Erbay et al. (2003) showed that mTOR signaling, which is downstream of Akt, is important for IGF-II induction during early phase of myogenic differentiation (3 h after differentiation was induced). However, further studies are needed to further clarify this issue.

IGFBP-5 is not only secreted but can also enter the nucleus in certain cell type (Firth and Baxter, 2002). We have recently reported that IGFBP-5 contains a functional transactivation domain in its conserved N-domain and this activity is IGF-binding independent (Xu et al., 2004; Zhao et al., 2006). Furthermore, full-length IGFBP-5 has transcriptional repressing activity (Zhao et al., 2006). Our finding that IGFBP-5 knockdown suppresses IGF-II mRNA expression in differentiating muscle cells raised the possibility that IGFBP-5 may exert direct an effect on IGF-II gene transcription in the nucleus. Two approaches were taken to address this intriguing hypothesis. First, immunocytochemical staining experiments showed that endogenous IGFBP-5 protein was detected in the Golgi apparatus and on the cell surface but not in the nuclei in myoblasts. Second, expression of the IGFBP-5 transactivation domain did not cause any significant change in IGF-II mRNA expression levels. These results argue against a direct action of IGFBP-5 on the IGF-II gene transcription in this cell type.

It is of interest to find that IGF-II up-regulates its own gene expression in differentiating C2C12 myoblasts. Although previous studies have indicated that nutrients influence IGF-II gene expression in C2C12 cells through the PI3K-Akt-mTOR pathway (Erbay et al., 2003), to our knowledge, this is the first demonstration that IGF-II stimulates its own gene expression in skeletal muscle cells. Furthermore, forced expression of a constitutive Akt strongly increases IGF-II expression in these cells, suggesting that IGF-II auto-regulates itself through activating the IGF-IR-PI3K-Akt signaling pathway in C2C12 cells. This and other findings led us to propose a new model, depicted in Fig. 10 D, on how IGFBP-5 acts to promote myogenic differentiation. According to this model, the induction of IGFBP-5 in early stages of myogenic differentiation plays a crucial role in promoting the myogenic action of autocrine IGF-II. IGFBP-5 acts by binding to IGF-II and promoting its interaction with IGF-IR. This interaction may contribute to reaching a certain threshold that turns on the IGF-II positive auto-regulatory loop, thereby resulting in increased IGF-II gene expression. The increase in IGF-II production, in turn, results in an accelerated elevation in the IGF-IR-PI3K-Akt signaling activity, leading to increases in Myogenin, MHC expression, and myotube formation. This model is supported by several lines of evidence. First, IGFBP-5 is induced in early stages of myogenesis, before the elevation of IGF-II expression, in the C2C12 myoblast model...
and in primary cells. Second, knockdown of IGFBP-5 impairs myogenic differentiation. Third, knockdown of IGFBP-5 suppresses IGF-II gene expression and addition of exogenous IGF-II “rescues” IGFBP-5 knockdown-induced myogenic defects. Furthermore, we show that IGF-II up-regulates its own gene expression via the PI3K-Akt signaling pathway. Addition of native IGFBP-5 but not a ligand binding IGFBP-5 mutant, together with a low concentration of IGF-II, restores IGF-II expression and myogenic differentiation.

Although it is known that IGFBP-5 has IGF-independent actions (Clemmons, 2001; Duan, 2002; Firth and Baxter, 2002), the myogenic promotion action of IGFBP-5 is clearly IGF-dependent: (1) immunocytochemistry revealed that endogenous IGFBP-5 is not localized to the nuclei of C2C12 cells; (2) adding high concentrations of exogenous IGF-I or IGF-II reversed IGFBP-5 knockdown caused myogenic defects; (3) Des(1-6)IGF-II has lower activity in regulating differentiation; and (4) adding native IGFBP-5, but not the LBD mutant IGFBP-5, rescued the myogenic defects in the presence of low concentrations of IGF-II. It has been shown that IGFBP-5 is not only present in the extracellular fluids, but is also localized on the cell surface and/or extracellular matrix (Clemmons, 2001). In this study, we have provided two lines of independent evidence indicating that abundant amounts of intact IGFBP-5 is indeed located on the surface of differentiating myoblasts and is capable of IGF binding. It is possible that cell-surface associated IGFBP-5 provides a means of attracting IGF-II to the close proximity of the IGF-IR receptor, thereby enhancing IGF-II signaling activity and initiating the IGF-II positive auto-regulation loop.

In summary, we have uncovered a novel mechanism by which the induction of IGFBP-5 promotes the myogenic action of autocrine IGF-II. We provide evidence suggesting that IGFBP-5 is located on the cell surface and binds to autocrine IGF-II and potentiates its interaction with IGF-IR, leading to the enhanced activation of the IGF-IR-PI3K-Akt signaling activity and a further increase in IGF-II gene expression. An accelerated activation of this auto-regulatory loop stimulates muscle cell differentiation after reaching a certain threshold. We have extended these findings to primary cultures, suggesting that this mechanism is of physiological relevance.

Materials and methods

Materials and animals

Monoclonal MHC antibody (MF20) was purchased from the Developmental Studies Hybridoma Bank (Iowa City, IA); Antibodies against MyoD (M-318) and Myogenin (M-225) were purchased from Santa Cruz Biotechnology, Inc., and antibodies to Akt and phosho-Akt (Ser473) were from Cell Signaling Technology. Monoclonal anti-tubulin antibody (T6793) was from Sigma-Aldrich. The secondary antibody conjugates were purchased from Jackson ImmunoResearch Laboratories. Recombinant human IGF-I, IGF-II, Des(1-6)IGF-II, and IGFBP-5 were purchased from R and D System. Fetal bovine serum (FBS), horse serum (HS), DMEM, OPTI-minimum essential medium were purchased from Invitrogen. iQ SYBR Green Supermix was from Bio-rad Laboratories. All other chemicals were reagent grade and were purchased from Thermo Fisher Scientific unless otherwise noted. Mice [strains C57BL/6J] were obtained from Charles River Laboratories.

Plasmid construction

pSUPER Vector was provided by Dr. Reuven Agami (Netherlands Cancer Institute). The construction and verification of pSUPER-BP5, which generates IGFBP-5 siRNA, was described previously (Yin et al., 2004). A control pSUPER construct expressing siRNA with a sequence [TCTCGAGGATGAGATC, targeting the mouse TSC2 3′-terminal sequence] unrelated to IGFBP-5 was also used as a control. Mouse IGF-II cDNA and partial mouse IGFBP-5 cDNA were amplified by RT-PCR and cloned into the pGEM-T easy vector (Promega). Myogenin plasmids (pc52MTMyogenin and pCS2EGFP) and the Myogenin reporter construct 400x and control TK reporter construct (Tang et al., 2004) were provided by Dr. Daniel Goldman [University of Michigan]. MyoD cDNA was a gift from Dr. Lasser Andrew (Harvard Medical School). The pCS2-myrt-Akt construct, which expresses a constitutively active, membrane-localized full-length mouse Akt1 (Kohn et al., 1998), was provided by Dr. Anne Vojtek [University of Michigan]. pcdNA3.1-EGFP-mIGFBP5, which expresses a nonsecreted form of IGFBP-5 with EGFP tagged at its N terminus, was generated by inserting mature IGF-I (signal peptide deleted) into the pcDNA3.1+[+ vector. All of the plasmids were verified by DNA sequencing.

Cell culture and transfection

Mouse C2C12 cells were purchased from American Type Culture Collection (Manassas, VA) and cultured in DMEM supplemented with 10% FBS in a humidified air atmosphere containing 5% CO2. For transfection, 6 x 104 cells were seeded in 6-well plates (Falcon). 2 μg of pSUPER-BP5 or pSUPER plasmid DNA was transfected into cells as previously reported (Yin et al., 2004). 30 h after transfection, the cells were washed and incubated with fresh serum-free medium (SMF) for 48 h. At the end of incubation, the conditioned media and total RNA were prepared for further analysis. 3 h after transfection, the cells were washed with SMF and then transferred to differentiation medium (DM) consisting of DMEM plus 0.5–2% horse serum. For rescue experiments, 30 h after transfection, the cells were switched to DM plus IGF-I, IGF-II, and/or IGFBP-5 with concentration designated in each experiment. Primary mouse skeletal myoblasts were isolated from approximately 2–5-d-old mice, grown, and differentiated following a previously reported method (Tang and Goldman, 2006). In brief, the forelimbs and hindlimbs were removed from neonatal mice. Muscle mass was minced into a coarse slurry and enzymatically dissociated at 37°C for 35–45 min with frequent trituration. Isolated muscle cells were grown in DMEM supplemented with 10% FBS and 10% HS on collagen-coated plates at a density of 2–4 x 104 cells per 35-mm culture dish. PuGene (Roche) was used for transfection of these primary cells. Differentiation was induced by switching to DMEM medium containing 5% or 1% HS. All experiments were conducted in accordance with guidelines approved by the University Committee on the Use and Care of Animals (University of Michigan).

Northern blot

Total RNA was extracted using TriPure Reagent following the manufacturer’s instructions. RNA samples were size-fractionated in 1.2% agarose gels, blotted, and fixed onto Hybond N membranes (GE Healthcare). Hybridization was performed using 32P-dCTP-labeled (MP Biomedicals) IGFBP-5 or IGFBP4 cDNA probes as reported previously (Duan et al., 1996). Labeled GAPDH cDNA was used as a control. The band densities were quantified using Quantity One quantification software (Bio-Rad Laboratories).

Reverse transcription (RT)-PCR and quantitative real-time RT-PCR (qRT-PCR)

After treated with DNase, RNA samples were subjected to reverse-transcription using SuperScript II reverse transcriptase (Invitrogen). Gene specific primers for IGF-I, IGF-I receptor, IGFBP2, IGFBP4, and S17 were described previously (Wilson et al., 2003; Boutinaud et al., 2004). IGF-II primers for RTPCR are 5′-GGTTCTCACTCTACACCCG-3′ (sense), 5′-GGTGTTAACCACGATACGGGC-3′ (antisense). The linear range of product amplification was established in pilot studies for each primer pair.

qRT-PCR was performed using an iCycler IQ Multicolor real-time PCR detection system (Bio-Rad Laboratories). Primer sequences for qRT-PCR were provided by others (Boutinaud et al., 2004). 4 μl of the cDNA product (1:20 dilution) was used as a PCR template. Plasmid cDNA for cyclin D1 was purchased from Clontech Laboratories. A housekeeping gene, was provided by Dr. Gregor Sutcliffe (Scripps Research Institute). Serial dilutions of the plasmids ranging from 10 to 10 molecules/2 μl were used for standard curve. The number of molecules of particular gene transcript was calculated based on the standard curve and normalized to the cyclin D1 mRNA level.
The specificity of the PCR was verified by denaturing curve analysis and direct sequencing of the products.

Immunohistochemistry

Cells cultured on 6-well dishes were washed twice with 1x PBS before fixation in 4% paraformaldehyde for 10 min. Cells were permeabilized for 5 min in 1x PBS containing 0.2% Triton X-100 (PBST), washed twice with PBST, and incubated with primary antibodies at 4°C overnight. The cells were next washed three times with PBST before incubation with Cy3-conjugated secondary antibodies for 2 h at room temperature. For experiments that required intact membrane integrity, staining was performed in 1x PBS without detergent. Immunofluorescence or phase-contrast images were obtained at room temperature using a microscope (Eclipse E600; Nikon) with Plan Fluor 10x/0.3 or 20x/0.5 dry objectives. Images were acquired using a camera (DC500N; Nikon) and Scion acquisition software. Images were processed with Photoshop for overlay. A Leica SP5 microscope with HCX PL APO CS 40.0 × /0.85 dry objective was used for confocal imaging.

Western and ligand blot analysis

Equal amounts of protein were separated by SDS-PAGE and transferred to Immobilon P membranes (Millipore) and subjected to Western blot following published procedures (Duan et al., 1996). The antibodies were used at concentrations recommended by the commercial sources. Ligand blot analysis was performed using digoxigenin-labeled IGFI following published procedure (Yin et al., 2004). To determine cell surface–bound IGFBP-5, cultured cells were washed in 1x PBS twice and then incubated briefly in a high salt buffer (20 mM NaCl).

 Luciferase reporter assay

The transcription activity of Myogenin was determined using the dual luciferase reporter assay kit (Promega). In brief, myoblasts were cotransfected with pC2SMMyogenin or pC2S plasmid, 4RTK or control minimal TK reporter, and a fellowship from the Changjiang Scholars Program.

Statistical analysis

Differences among groups were analyzed by t test or one-way analysis of variance followed by Tukey post test, using Prizm (GraphPad Software, Inc.). Significance was accepted at P < 0.05.

We thank Drs. D. Clemmons, R. Agami, G. Sutcliffe, D. Goldman, L. Andrew, and A. Vogel for providing reagents for this work. We are very grateful to Dr. Huibin Tang (University of Michigan), for his advice on primary muscle cell cultures. We also thank John Allard and Justin Lenthart for proofreading this manuscript.

This study was supported by National Institutes of Health Grant 2RO1HL66079, National Science Foundation Research Grant ICB 0110864, and a fellowship from the Chiangjiang Scholars Program.
