The mitotic spindle mediates inheritance of the Golgi ribbon structure

Jen-Hsuan Wei and Joachim Seemann
Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX 75390

The mammalian Golgi ribbon disassembles during mitosis and reforms in both daughter cells after division. Mitotic Golgi membranes concentrate around the spindle poles, suggesting that the spindle may control Golgi partitioning. To test this, cells were induced to divide asymmetrically with the entire spindle segregated into only one daughter cell. A ribbon reforms in the nucleated karyoplasts, whereas the Golgi stacks in the cytoplasts are scattered. However, the scattered Golgi stacks are polarized and transport cargo. Microinjection of Golgi extract together with tubulin or incorporation of spindle materials rescues Golgi ribbon formation. Therefore, the factors required for postmitotic Golgi ribbon assembly are transferred by the spindle, but the constituents of functional stacks are partitioned independently, suggesting that Golgi inheritance is regulated by two distinct mechanisms.

Introduction

The Golgi apparatus in mammalian cells consists of stacks of flattened cisternae that are linked together laterally into a single continuous ribbon in the perinuclear region. As the central hub of the secretory pathway, the Golgi receives newly synthesized proteins from the ER and sorts them into their correct cellular destinations. The orientation of the Golgi ribbon directs exocytosis toward a particular area of the plasma membrane and thereby facilitates the establishment of cell polarity, for instance, during wound healing (Preisinger et al., 2004), neural development (Horton et al., 2005), and immune response (Stinchcombe et al., 2006).

During cell division, the single Golgi ribbon needs to be segregated into the two daughter cells. To achieve partitioning, the Golgi fragments at the onset of mitosis, and later reforms in each daughter cell (for review see Lowe and Barr, 2007). Two different mechanisms have been proposed for the partitioning of the Golgi. In one view, Golgi membranes are absorbed into and partitioned with the ER (Zaal et al., 1999). The second view argues that the Golgi remains distinct from the ER and that the two compartments are inherited independently (Bartz and Seemann, 2008). In this scenario, the spindle has been proposed as the machinery responsible for Golgi partitioning based on the observed accumulation of Golgi membranes at the spindle poles (Shima et al., 1998), although a pool of membranes is dispersed throughout the cytoplasm (Jesch et al., 2001).

To elucidate the role of the spindle in Golgi partitioning, we established an assay in which the entire spindle is segregated into only one daughter cell. Upon division, a Golgi ribbon reformed in the karyoplasts, whereas the stacked cisternae were scattered throughout the cytoplasm. We could rescue ribbon assembly in the cytoplasts by microinjecting the Golgi extract together with tubulin or by lowering the division temperature, at which partial spindle materials were transferred into the cytoplasm. We propose that Golgi factors required for ribbon assembly rely on the spindle for partitioning, but functional stacks are inherited independently. This reveals two levels of regulation underlying Golgi inheritance. Coupling of these factors with the spindle would ensure that daughter cells receive the information to assemble the Golgi ribbon, which is vital for cellular functions that require polarized secretion and directional migration.

Results and discussion

To evaluate the role of the spindle in Golgi partitioning, we first examined the spatial correlation between Golgi membranes and the spindle. Consistent with previous studies (Shima et al., 1998; Jokitalo et al., 2001), we found Golgi membranes concentrated in metaphase around the two spindle poles in a variety of cell lines, including HeLa, Vero, LLC-PK1, normal rat kidney, and PtK1 (unpublished data). The association was prominent in...
PtK1 cells and was observed for both the stably expressed GFP-tagged Golgi enzyme N-acetylglucosaminyl transferase I (NAGT I) and the endogenous Golgi matrix protein GM130 (Fig. 1, B and C). We occasionally observed aberrant monopolar, tripolar, and tetrapolar spindles and Golgi membranes clustered at the spindle poles as well (Fig. 1, D–F). Moreover, accumulation of Golgi at the spindle poles was still evident when PtK1 cells were treated with the Eg5 inhibitors monastrol (Mayer et al., 1999) or trityl-cysteine (Skoufias et al., 2006) to induce monopolar spindles (Fig. 1, G and H). Collective, these data suggest a robust association of mitotic Golgi membranes with the spindle apparatus.

To test whether the spindle is required for Golgi partitioning, we established a system in which mitotic cells were induced to divide asymmetrically into two daughter cells, but only one of which received the entire spindle (Fig. 2 A). PtK1 cells stably expressing NAGT I–GFP were treated with an Eg5 inhibitor, either monastrol or trityl-cysteine. Upon entry into mitosis, inhibition of the kinesin Eg5 blocks centrosome separation, leading to the formation of monoasters and the arrest of cells in M phase (Mayer et al., 1999). Monoasters consist of microtubules emanating from nonseparated centrosomes and are surrounded by condensed chromosomes. Because PtK1 cells remain relatively flat during mitosis, monoasters are often asymetrically located at one side of the cells (Canman et al., 2003). We induced cell division by two independent methods. We microinjected recombinant Mad1 to sequester Mad2 from the kinetochores, which silences the spindle checkpoint and allows progression through mitosis (Canman et al., 2003). We also found that asymmetrical cell division could be induced by inhibition of Cdk1 with roscovitine or purvalanol A (Niiya et al., 2005; Hu et al., 2008). Both approaches generated a cytoplast without a nucleus and a nucleated karyoplast. Daughter cells were either identified by the injection marker (Mad1 injection) or monitored by time-lapse phase-contrast microscopy (Cdk1 inhibition).

After division, the karyoplasts received the chromosomes (Fig. 2, E and I), centrodesomes (unpublished data), and microtubules (Fig. 2, D and H), whereas the cytoplasts lacked all of these. Intriguingly, Golgi markers, including NAGT I–GFP and GM130, were detected in both cells (Fig. 2, C and G), suggesting that parts of the Golgi were partitioned independently of the spindle (n = 29 for Mad1 injection; and n > 50 for Cdk1 inhibition). However, the organization of the Golgi in the two daughter cells was very different. We analyzed the Golgi distribution in each daughter cell, where the Golgi was determined as a ribbon if 90% of the fluorescence resided in no more than three continuous structures (Putthaveedu et al., 2006). The Golgi stained in the karyoplasts localized to the perinuclear region and exhibited the characteristic ribbon structure (Fig. 2, C and G). In contrast, the Golgi in the cytoplasts was spread throughout the cytoplasm and failed to reform a ribbon (Fig. 2, C and G). This indicates that the spindle has a direct role in inheritance of the Golgi ribbon.

To eliminate the possibility that the scattered Golgi in the cytoplasts might be caused by cell death, we followed both karyoplasts and cytoplasts by video microscopy. The cytoplasts survived on average 36 h after division and, in some cases, were still alive and seemingly healthy when corresponding karyoplasts underwent a second round of cell division.

The scattered Golgi and the absence of microtubules in the cytoplasts are reminiscent of cells treated with nocodazole, which causes the Golgi ribbon to fragment into stacks that are dispersed throughout the cell (Shima et al., 1998). Our EM analysis revealed that the Golgi in both karyoplasts and cytoplasts was stacked with an average of 3.4 ± 0.7 (karyoplast; n = 23) and 3.3 ± 0.6 (cytoplast; n = 23) cisternae per stack (Fig. 3, A and B). The cisternae were stacked to a comparable extent and separated by 11.8 ± 3.8 (karyoplast) and 12.9 ± 3.7 nm (cytoplast). To determine whether the stacks were polarized, we took advantage of a well-established fluorescence microscopy method (Shima et al., 1997). PtK1 cells stably expressing the medial/trans-Golgi enzyme NAGT I–GFP were induced to divide asymmetrically and immunolabeled for GFP and the cis–Golgi marker GM130 (n = 15). In these triple-labeled cells, the GFP fluorescence was first overlaid with the anti-GFP signal (Fig. 3, C and D) and was then overlaid with the anti-GM130 signal (Fig. 3, E and F). The anti-GFP staining served as a control, showing a complete overlap with the GFP fluorescence (Fig. 3, C and D). In contrast, the cis–anti-GM130 signal in the karyoplasts was found adjacent to the medial/trans-GFP fluorescence with only a partial overlap (Fig. 3 E), suggesting that the ribbon in the karyoplasts preserved a
cis-to-trans polarity. A similar segregation pattern was observed in the cytoplasts (Fig. 3 F). Together with our EM data, we conclude that the scattered Golgi in the cytoplasts is stacked and polarized.

We next investigated whether the stacked Golgi in the cytoplasts transports cargo. The mRNA of CD8, a plasma membrane protein not expressed in PtK1 cells, was injected together with Mad1 protein into cells with asymmetrical monoasters. Cells were incubated for 4 h to allow cell division, as well as synthesis and transport of cargo, and were fixed and stained before permeabilization. CD8 was detected on the cell surface in both karyoplasts and cytoplasts (n = 22; Fig. 3 H) but not in cells with impaired secretion (Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200809090/DC1), indicating that the Golgi stacks in both cells transported cargo. To rule out that CD8 might have been expressed and transported before cytokinesis, we induced asymmetrical cell division in the presence of the protein synthesis inhibitor cycloheximide. After the drug was removed to allow protein expression and transport, CD8 was detected on the cell surface of both cells (n = 9; unpublished data). In another approach, we injected CD8 mRNA into the cytoplasts generated by Cdk1 inhibition. CD8 appeared on the cell surface of the cytoplasts but not on the noninjected karyoplasts (n = 8; Fig. 3 L). Similarly, myc-tagged protein A fused to the transmembrane domain of the PDGF receptor was also delivered to the cell surface (n = 15; Fig. S1 K). These findings indicate that the Golgi stacks in the cytoplasts are functional for secretion and do not require the spindle for partitioning.

In principle, the lack of a Golgi ribbon in the cytoplasts could be explained by two different mechanisms. First, the failure in ribbon assembly might be a result of the absence of microtubules in the cytoplasts because microtubules are essential to establish a Golgi ribbon. In this case, reformation of microtubules should restore the ribbon. Alternatively, the scattered Golgi stacks in the cytoplasts might be caused by the exclusion of the factors required for ribbon assembly (i.e., ribbon determinants). Ribbon determinants may associate with Golgi membranes, and therefore not transferred to the cytoplasts. Supplying these factors should rescue ribbon formation. To distinguish between these two possibilities, we injected the missing materials into the cytoplasts and examined the Golgi morphology. Injection of tubulin resulted in a microtubule network (Fig. 4 C), demonstrating that the cellular environment in the cytoplasts supports microtubule polymerization (Pelletier et al., 2000). However, the overall organization of Golgi stacks remained scattered (n = 14, five independent experiments; Fig. 4 B), indicating that the microtubules in the cytoplasts are not sufficient to reassemble a ribbon. Therefore, additional factors might be required but were presumably segregated along with the spindle into the karyoplasts. Because these factors may associate with Golgi membranes, we extracted rat liver Golgi (RLG) membranes with the nonionic detergent n-octylglucoside and removed the...
found that medial/trans-Golgi markers were enriched in the Golgi extract, whereas cis-Golgi proteins were mostly depleted (Fig. 4 O). This implies that the factors required for postmitotic ribbon reassembly might have distinct molecular compositions from the cis-Golgi proteins Golgin84, GRASP65, and GM130 shown to be required for ribbon maintenance in interphase (Diao et al., 2003; Puthenveedu et al., 2006).

If the ribbon determinants are partitioned with the spindle, incorporation of parts of the spindle and its associated proteins into the cytoplasts should rescue ribbon formation. We followed asymmetrical cell division induced at lower temperature (32 °C) and found that spindle positioning was dramatically altered, presumably caused by effects on microtubule dynamics (Fig. S2, available at http://www.jcb.org/cgi/content/full/jcb.200809090/DC1). At 37 °C, the monopolar spindle was positioned distal to the cleavage furrow and seemingly adhered to the cortex at one side of the cell (Fig. 5 A and Video 1). The cytoplasts derived from this type of division contained scattered Golgi but no microtubules (Fig. 2, G and H; and Fig. 5, B and C). However, at a lower temperature, the spindle was positioned centrally in close proximity to the division plane (Fig. 5 E).
that contained all the machinery required for protein synthesis (i.e., ribosomes) and exocytosis (i.e., ER and Golgi).

The cytoplasts received Golgi stacks capable of secretion independently of the spindle, but these stacks were not linked into a ribbon. This is in contrast to the karyoplasts, in which a ribbon reformed. Collectively, our data suggest two distinct mechanisms underlying Golgi inheritance. First, minimum functional Golgi units (stacks) are inherited in a spindle-independent manner. These stacks could be derived from Golgi that was partitioned together with the ER (Zaal et al., 1999) or could have reassembled from the Golgi that was segregated independently of the spindle (Jesch et al., 2001). Second, the mitotic spindle plays a vital role in transmitting ribbon determinants into the daughter cells.

The appearance of the Golgi ribbon in higher organisms during evolution reflects a different mechanism for polarized...
secretion. In lower animals such as *Drosophila melanogaster*, Golgi stacks are scattered and localized adjacent to ER exit sites despite the presence of centrosomes. Polarized secretion is achieved by targeting mRNA to specific ER exit sites where the cargo is made and secreted locally (Hepers and Rabouille, 2004). However, in mammalian cells, cargo is posttranslationally sorted from the centrally located Golgi ribbon (for review see Bard and Malhotra, 2006). To establish cell polarity, the entire Golgi ribbon is reoriented toward the site of secretion (Bisel et al., 2008), which is essential for a variety of cellular processes such as the outgrowth of dendrites in neurons (Horton et al., 2005), fibroblast migration during wound healing (Presingier et al., 2004), and the immune response (Stinchcombe et al., 2006). Because the ribbon is particularly important for more advanced functions, tight coupling of ribbon determinants with the spindle ensures that each daughter cell receives the information to assemble it. This might be the reason that mammalian cells use the highly regulated spindle apparatus to partition these factors instead of a stochastic ER-dependent process.

**Materials and methods**

**Antibodies**

The following antibodies were used: mouse monoclonal antibodies against GM130, Golgin94, TGN38, G515, G528, Vti1a (BD), CD8 (Wang et al., 2008), α-tubulin (TAT1; provided by K. Gull, University of Oxford, Oxford, England, UK), FITC-conjugated α-tubulin (DM1A; Sigma-Aldrich), dynern intermediate chains (74.1; Millipore), and nuclear pore complex (Mab414; Abcam). Rabbit polyclonal antibodies against GPP, S1P (Bartz et al., 2001) GRASP65 (provided by Y. Wang, University of Michigan, Ann Arbor, MI), pericentrin (Abcam), PDI (Assay Designs), Man I (provided by F. Barr, University of Liverpool, Liverpool, England, UK), Man II (provided by G. Warren, University of Vienna, Vienna, Austria), β-COP (EAGIE; provided by R. Pepperkok, European Molecular Biology Laboratory, Heidelberg, Germany), p243 (provided by T. Nielsson, University of Gothenburg, Gothenburg, Sweden), syntaxin 5 (provided by A. Price, Yale University, New Haven, CT), Rab1, giantin (provided by M. Beard, Yale University, New Haven, CT), Rab6, and myc (Santa Cruz Biotechnology, Inc.) were used. Sheep polyclonal antibodies against rat serum albumin (provided by G. Warren) were used. Polyclonal antibodies were raised in rabbits against GST fusion proteins of mouse Golgin45 (residues 1–123), rat GRASP55 (residues 232–454), and rat GM130 (residues 1–73 [N73]). N73-specific antibodies were affinity purified using His-tagged N73 covalently attached to Ni2+/H9251-hydroxysuccinimide–activated Sepharose (GE Healthcare). Goat anti–rabbit and goat anti–mouse antibodies conjugated to Alexa Fluor 488, 555, 594, or 647 were obtained from Invitrogen, and HRP-conjugated secondary antibodies were obtained from Thermo Fisher Scientific.

**Cell line, tissue culture conditions, and drug treatments**

Rat kangaroo kidney cells (PtK1) stably expressing NAGT I–GFP (Jokitalo et al., 2001) were grown in medium A (F-12 medium, 100 U/ml penicillin, 100 μg/ml streptomycin, 2 mM glutamine (Invitrogen), and 10% fetal calf serum (HyClone)), with 300 μg/ml G418 (EMD) at 37°C and 5% CO2. For live cell imaging, microinjections, immunofluorescence, and EM, PtK1 cells were grown on glass coverslips coated with Alcian blue BGX (Sigma–Aldrich). To arrest cells in mitosis with monasters, PtK1 cells were incubated for 2 h with an inhibitor of the kinesin Eg5, either 200 μM monastrol (BIOMOL International LP) or 20 μM Struyl-cysteine (Acros Organics). To induce cell division, a Cdk1 inhibitor, either 50 μM ruxacovastine (EMD) or 25 μM purvalanol A (EMD), was added to medium. Microinjections of CD8 or myc–PDGF receptor mRNA and tubulin and/or Golgi extract were performed 2 h after addition of purvalanol A.

**Protein purification and Golgi extraction**

The oligomerization and Mad2-binding domain of Mad1 (residues 321–556; Canman et al., 2003) was cloned from IMAGE clone 4299982 (American Type Culture Collection) into pGEX4-T3 (GE Healthcare) purified on glutathione–Sepharose 4B (GE Healthcare), dialyzed against injection buffer (20 mM Heps, pH 7.4, and 50 mM KOAc), and concentrated on a filter unit (Centricon YM-30; Millipore). RLG membranes were purified as described previously (Wang et al., 2008). In brief, rat liver was homogenized in 0.5 M sucrose in PM buffer (potassium phosphate, pH 6.7, and 5 mM MgCl2) with protease inhibitor cocktail (Roche). The homogenate was layered on top of 0.86 M sucrose, overlaid with 0.25 M sucrose, and centrifuged for 60 min at 29,000 rpm in a rotor (SW-41; Beckman Coulter). The 0.5 M sucrose layer was collected (cytosol fraction). The intermediate fraction was diluted to 0.25 M sucrose and layered on top of 1.3 and 0.5 M sucrose. After centrifugation for 30 min at 8,000 rpm in a rotor (SW-41), the enriched RLG membranes were collected at the 0.5/1.3 M sucrose interface. For microinjection experiments, RLG membranes were pelleted by centrifugation at 13,000 rpm for 10 min at 4°C, washed three times with injection buffer, extracted for 15 min on ice with 10% n-octylglucoside (EMD), and centrifuged at 13,000 rpm for 10 min at 4°C. The pellet was solubilized in sample buffer (pellet fraction), and the supernatant was dialyzed (10kD cut off) against injection buffer (supernatant fraction), centrifuged again, and concentrated on a filter unit (Centricon YM-10; Millipore). Tubulin purified from bovine brain was provided by M. Kikkawa (Kyoto University, Kyoto, Japan).

**In vitro transcription of mRNA**

The expression plasmid pdIpDA was generated by subcloning the coding sequence of protein A into pDisplay (Invitrogen) between the signal sequence and the myc epitope followed by the transmembrane domain of the PDGF receptor. Linearized pCD8 (Wang et al., 2008) and pdIpDA were transcribed in vitro using the mMESSAGE mMACHINE 17 Ultra kit (Applied Biosystems). Capping, poly(A) tailing reactions, and recovery of the mRNAs by U1 precipitation were performed according to the manufacturer’s instructions.
Microinjection and live imaging
For time-lapse microscopy and microinjection experiments, cells were incu-
bated in medium A containing 50 mM Hepes, pH 7.4. Microinjection was per-
formed with a microinjector (Transkaryot 52046 or Femtotol; Epp-
dendorf) and a micromanipulator (5171; Eppendorf) connected to a micro-
scope (Axiovert 200M; Carl Zeiss, Inc. ; Bartz and Seemann, 2008). The
reagents were injected at the following concentrations: 1.5 mg/ml
Mad1 or Sor1td (Bartz and Seemann, 2008), 0.2 mg/ml pCD8, 0.3 mg/ml
CD8 or myc–PDGF receptor mRNA, 6 mg/ml tubulin, and 20 mg/ml
Golgi extract. Mad1 was injected together with 2.5 mg/ml biotin-
search and is supported by a grant from the American Heart Association

Figure S1. Transport of newly synthesized proteins to the cell surface. (A–I) PtK1 cells stably expressing NAGT-I-GFP were microinjected with a plasmid encoding CD8 alone (A–F) or together with Sar1dn protein (G–I). 3 h after expression, cells were labeled for CD8 on the cell surface without permeabilization (A–C) or fixed and permeabilized before staining for CD8 (D–I). The Golgi was visualized by GFP, and DNA was stained with Hoechst. (A–C) CD8 was detected on the cell surface of nonpermeabilized cells. (D–F) In permeabilized cells, CD8 was detected in the Golgi in addition to the plasma membrane. (G–I) Sar1dn blocked transport to the cell surface, and CD8 was retained in the ER. (J–M) Secretion is functional in the cytoplasts. Asymmetrical cell division was induced by Cdk1 inhibition and followed by video microscopy (J). The cytoplasts were microinjected with the mRNA of myc-tagged protein A fused to the transmembrane domain of the PDGF receptor (PDGFR). 2 h after expression, cells were stained for myc without permeabilization. The Golgi was visualized by GFP, and DNA was stained with Hoechst. Cytoplasts are marked by asterisks, and the arrows indicate karyoplasts. Note that myc-PDGFR receptor was transported to the plasma membrane. Bars, 10 µm.
Figure S2. **Temperature affects spindle positioning during division.** Unsynchronized PtK1 cells were treated with trityl-cysteine for 2 h. Cell division was followed by time-lapse phase-contrast microscopy after addition of purvalanol A. In cells that entered mitosis at 37°C, the monopolar spindle was positioned distal to the cleavage furrow. At 32°C, the spindle was positioned centrally in close proximity to the cell division plane. For each experiment, 285 nonoverlapping microscopic fields were monitored to ensure unbiased sampling. Error bars represent SEM from two independent experiments with a mean of 50 cells per condition.

Video 1. **At 37°C, the spindle is positioned distal to the cleavage furrow.** PtK1 cells arrested with trityl-cysteine (2 h) were induced to divide asymmetrically with purvalanol A at 37°C and followed by time-lapse phase-contrast microscopy. Images were captured every 10 min for 2 h and displayed at 2.5 frames per s.

Video 2. **At 32°C, the spindle is positioned close to the cleavage furrow.** PtK1 cells arrested with trityl-cysteine (2 h) were induced to divide asymmetrically with purvalanol A at 32°C and followed by time-lapse phase-contrast microscopy. Images were captured every 12 min for 2 h and displayed at 2.5 frames per s.
