Abbreviations used in this paper: CH, calponin homology; MAP, MT-associated protein; MOM, mouse on mouse; MT, microtubule; wt, wild type.

C ytolinkers are giant proteins that can stabilize cells by linking actin filaments, intermediate filaments, and microtubules (MTs) to transmembrane complexes. Dystrophin is functionally similar to cytolinkers, as it links the multiple components of the cellular cytoskeleton to the transmembrane dystroglycan complex. Although no direct link between dystrophin and MTs has been documented, costamere-associated MTs are disrupted when dystrophin is absent. Using tissue-based cosedimentation assays on mice expressing endogenous dystrophin or truncated transgene products, we find that constructs harboring spectrinlike repeat 24 through the first third of the WW domain cosediment with MTs. Purified Dp260, a truncated isoform of dystrophin, bound MTs with a Kd of 0.66 µM, a stoichiometry of 1 Dp260/1.4 tubulin heterodimer at saturation, and stabilizes MTs from cold-induced depolymerization. Finally, α- and β-tubulin expression is increased ~2.5-fold in mdx skeletal muscle without altering the tubulin–MT equilibrium. Collectively, these data suggest dystrophin directly organizes and/or stabilizes costameric MTs and classifies dystrophin as a cytolinker in skeletal muscle.

Introduction

The plakins are a class of giant cytolinker proteins that can link transmembrane protein complexes to the actin, intermediate filament, and microtubule (MT) cytoskeletons in various combinations (Fuchs and Karakesisoglou, 2001). Plakins can bind actin filaments via tandem calponin homology (CH) domains, intermediate filaments via plakin repeat domains, and MTs through either a Gas2-related domain or a glycine/serine/arginine domain (for review see Leung et al., 2002). The ability to cross-link multiple components of the cellular cytoskeleton allows cytolinkers to stabilize cells from mechanically induced damage. Mouse knockout studies exemplify the stabilizing effects of cytolinkers, as loss of the cytolinker plectin resulted in skin blistering and a form of muscular dystrophy (Andra et al., 1997), and ablation of BPAG-1, another cytolinker, caused skin blistering upon mechanical stimulation (Guo et al., 1995).

Dystrophin, the protein absent in patients with Duchenne muscular dystrophy (Hoffman et al., 1987), shows structural and functional similarities to cytolinkers, which suggests the hypothesis that dystrophin performs a cytolinker role in muscle. Dystrophin’s large molecular mass of 427 kD, spectrinlike repeats, and ability to bind actin filaments via a tandem CH domain (Way et al., 1992) highlight three similarities with cytolinkers. Although dystrophin lacks a plakin repeat domain, dystrophin–intermediate filament interactions have been documented (Stone et al., 2005; Bhosle et al., 2006). Thus, the ability to link the actin and intermediate filament cytoskeletons to the transmembrane dystroglycan complex (Suzuki et al., 1992) illustrates how dystrophin functions similarly to other cytolinkers. Finally, the muscle membrane fragility associated with the loss of dystrophin (Petrof et al., 1993) parallels the structural deficiencies observed in other cytolinker-deficient tissues, further demonstrating a close relationship between dystrophin and other cytolinkers. Collectively, these data support the hypothesis that dystrophin may function as a cytolinker in skeletal muscle.

Although dystrophin exhibits many characteristics of a cytolinker, a direct dystrophin–MT interaction has not been documented. Dystrophin lacks either a Gas2-related or a glycine/serine/arginine domain, but recent studies indicated that dystrophin at least indirectly influences MT organization or stability (Percival et al., 2007; Ayalon et al., 2008). For instance, the dystrophin-deficient mdx mouse exhibited MT disorganization in skeletal muscle with the costameric MTs most severely affected (Percival et al., 2007). Dystrophin’s enrichment at costameres

and the restoration of costameric MT organization through virally mediated expression of a microdystrophin (Percival et al., 2007) indicates that dystrophin is necessary for proper costameric MT organization in skeletal muscle. Moreover, acute knockdown of ankyrin-B, a protein necessary for delivery of dystrophin to the sarcolemma and neuromuscular junction, caused the loss of costameric MTs and aberrant MT organization in a subset of MTs underlying the neuromuscular junction (Ayalon et al., 2008).

In this study, we investigated the hypothesis that dystrophin directly interacts with costameric MTs. We confirmed that costameric MTs were disrupted in dystrophin-deficient skeletal muscle and showed endogenous dystrophin cosedimented with MTs in tissue homogenates. Using purified proteins, we found that the carboxyl-terminal two thirds of dystrophin bound MTs with a Kd of 0.66 µM and stabilized MTs from cold-induced depolymerization. Finally, we documented a 2.5-fold increased expression of α- and β-tubulin without alteration in the tubulin–MT equilibrium in mdx skeletal muscle. These results demonstrate that dystrophin is a MT-associated protein (MAP) that stabilizes costameric MTs and functions as a costameric cytolinker in skeletal muscle.

Results and discussion

To determine whether dystrophin and MTs localize to similar structures in skeletal muscle, we conducted immunofluorescence analysis on teased extensor digitorum longus muscle fibers co-labeled with antidystrophin and anti–α-tubulin antibodies (Fig. 1, A and B). Dystrophin forms a subsarcolemmal network with transverse components along the I bands and the M line and with longitudinal components (Williams and Bloch, 1999), whereas MTs form a subsarcolemmal lattice, which in fast fibers, has transverse and longitudinal components plus an accumulation of MTs around myonuclei (Ralston et al., 1999). We found that the transverse MTs (Fig. 1 A, arrowheads) weave their course along the I band dystrophin staining for long distances. MTs were also transverse MTs (Fig. 1 A, arrowheads) weave their course along the I band dystrophin staining for long distances. MTs were also transverse MTs (Fig. 1 A, arrowheads) weave their course along the I band dystrophin staining for long distances. MTs were also

Figure 1. Dystrophin guides MTs at the surface of the muscle fibers and is necessary for proper MT organization. (A) Isolated muscle fibers from the extensor digitorum longus of 7-wk-old wt mice were costained for dystrophin (left) and α-tubulin (middle). The right panel shows that MTs (red) follow dystrophin (green) bands for long distances both transversely (arrowheads) and longitudinally (arrows). (B) At a higher magnification, dystrophin staining is granular; MTs are studded with dystrophin “dots.” Arrows indicate longitudinal MTs that follow dystrophin. (C) Muscle fibers from the extensor digitorum longus of 7-wk-old wt, mdx, utrn−/−, and mdx/utrn−/− mice were stained with DM1A anti-α-tubulin and Hoechst dye. Both wt and utrn−/− fibers show the lattice of transverse and longitudinal MTs characteristic of fast fibers (arrowheads). In mdx and mdx/utrn−/− fibers, the regularity of the lattice is lost, and mostly oblique MTs originate from cytoplasmic nucleation points (arrows). (D) Peripherally nucleated prenecrotic fibers from 24-d-old mdx mice also displayed MT disorganization, indicating that MT derangement occurred before muscle cell necrosis and regeneration. Bars: (A and B) 10 µm; (C and D) 20 µm.
Next, we performed a tissue-based MT cosedimentation assay (Fig. 2 A) to determine whether dystrophin cosedimented with MTs. Under conditions that induced MT depolymerization, virtually no muscle protein pelleted (Fig. 2 B). However, numerous proteins pelleted under MT-stabilizing conditions, and this fraction of proteins represents MTs and the MAPs of skeletal muscle (Fig. 2 B). We Western blotted each fraction obtained from the tissue cosedimentation assay performed on wt mice expressing full-length dystrophin or transgenic mdx mice expressing Dp260, microdystrophin (ΔR4-R23), or Dp71 (Fig. 2 C, right). Full-length dystrophin, Dp260, and ΔR4-R23 all pelleted with MTs, whereas Dp 71 did not (Fig. 2 C, left). By comparing the dystrophin domains present or absent in each construct (Fig. 2 C, right) along with each construct’s ability to cosediment with MTs, we suggest that spectrinlike repeat 24 through the first third of the WW domain encodes a novel MT-binding domain.

To test for a direct interaction between dystrophin and MTs, we performed MT cosedimentation using two purified recombinant dystrophin constructs and purified tubulin. The two recombinant constructs used were Dp260, which encodes from spectrinlike repeat 10 through the carboxy terminus of dystrophin, including the proposed MT-binding domain, and DysNterm-R10 (Rybakova et al., 2006), which encodes the amino-terminal, tandem CH actin-binding domain and spectrinlike repeats 1–10 of the middle rod domain absent from Dp260. A small amount of Dp260 pelleted in the absence of MTs, but substantially more Dp260 shifted to the pellet fraction when MTs were present (Fig. 3 A). After substracting self-pelleting Dp260, Dp260 displayed a concentration-dependent and saturable cosedimentation with a Dp260/tubulin heterodimer stoichiometry of 1:1.4 and a Kd of 0.66 µM (Fig. 3 C). As predicted, DysNTerm-R10 did not cosediment with MTs up to concentrations approaching 10 µM (Fig. 3, B and C).

Next, we assessed how the presence of 1 µM Dp260 affected the tubulin–MT equilibrium in vitro. Dp260 had no significant effect on the fraction of tubulin in the MT fraction when incubated at room temperature (67.3 ± 0.72% vs. 68.6 ± 1.3%). However, the presence of Dp260 significantly increased the fraction of tubulin retained in the MT pellet (33.6 ± 2.9% vs. 42.2 ± 2.0%) when MTs were induced to depolymerize by incubating at 4°C (Fig. 3, D and E). Collectively, these results demonstrate that dystrophin directly binds and stabilizes MTs from cold-induced depolymerization.

Because misregulation of other MAPs can alter tubulin expression and MT stability (Harada et al., 1994; Takahashi et al., 2003), we investigated how the loss of dystrophin affects the regulation of tubulin expression and the tubulin–MT equilibrium in skeletal muscle fibers. Tubulin levels in wt and mdx skeletal muscle extracts were examined by quantitative Western blot analysis. With mAb B512, we observed no difference...
in α-tubulin expression in wt and mdx skeletal muscle extracts (Fig. 4, A and B), which was consistent with what we (Prins et al., 2008) and others (Barton et al., 2002) reported previously. However, mAb DM1A showed an ~2.5-fold increase in α-tubulin expression in mdx skeletal muscle (Fig. 4, A and B). Because levels of α- and β-tubulin are coregulated (Gonzalez-Garay and Cabral, 1995), we investigated β-tubulin levels to determine whether α-tubulin is up-regulated in mdx skeletal muscle. β-Tubulin expression was elevated 2.5-fold in mdx skeletal muscle (Fig. 4, A and B), suggesting that expression of both α- and β-tubulin is increased in mdx skeletal muscle. Thus, we conclude that mAb DM1A is able to recognize a population of α-tubulin not detected by mAb B512. To examine MT stability in mdx skeletal muscle, we analyzed levels of tyrosinated α-tubulin, a marker of dynamic MTs (Gundersen et al., 1984, 1987), and acetylated α-tubulin, a marker of long-lived MTs (Bulinski and Gundersen, 1991). The levels of tyrosinated α-tubulin were increased ~2.5-fold in mdx extracts (Fig. 4, A and B), whereas the levels of acetylated α-tubulin were not (Fig. 4, A and B). The loss of dystrophin’s MT-stabilizing ability may explain why acetylated α-tubulin was not more abundant in mdx skeletal muscle extracts, but alterations in the tubulin–MT equilibrium could also explain the lack of more stable MTs. Therefore, we examined the tubulin–MT equilibrium in wt and mdx skeletal muscles and found that the loss of dystrophin did not affect the equilibrium (Fig. 4, C and D). Collectively, these results show that tubulins are misregulated in dystrophin-deficient skeletal muscle without affecting the tubulin–MT equilibrium. The loss of dystrophin’s MT-stabilizing ability likely explains why there are not more stabilized MTs even in the presence of more tubulin dimer in dystrophin-deficient skeletal muscle.

An indirect link between dystrophin and MTs mediated by ankyrin-B was recently shown to be important for proper trafficking of dystrophin and β-dystroglycan to the sarcolemma (Ayalon et al., 2008). However, costameric MTs are disorganized in mdx skeletal muscle even in the presence of properly localized ankyrin-B (Ayalon et al., 2008). Because the MT- and ankyrin-B-binding domains of dystrophin do not overlap (Fig. 5), our results and previous results suggest that dystrophin interacts with MTs in vivo through two distinct mechanisms. We propose that ankyrin-B delivers dystrophin to the sarcolemma dependent on MTs and that dystrophin and ankyrin-B collaborate to stabilize and organize MTs in skeletal muscle.

As with other cytolinkers, the ability to bind multiple components of the filamentous cytoskeleton likely allows dystrophin to protect the sarcolemma from mechanically induced damage. One highly truncated microdystrophin construct (ΔR4-23) is very effective in restoring function in the dystrophin-deficient mdx mouse (Harper et al., 2002). Interestingly, the ΔR4-23 microdystrophin contains all sequences required for interaction with the three cytoskeletal filament systems: the amino- and carboxy-terminal domains CH domain, which binds actin (Way et al., 1992) and cyto-keratin filaments (Stone et al., 2005), the spectrinlike repeat 3 and the cysteine-rich regions, which are necessary for synemin intermediate filament binding (Bhosle et al., 2006), and the MT-binding domain. In contrast, Dp260 lacks the cyto-keratin filament–binding domain and portions of the synemin- and actin-binding domains, which likely alters the binding affinities to both actin and synemin filaments and may explain why transgenic overexpression of Dp260 only partially alleviates the mdx...
pathophysiology. For example, disorganized MTs are also associated with Golgi mislocalization (Percival et al., 2007), which in combination, would likely lead to impaired trafficking of membrane-bound proteins and may explain the decreased levels of β-dystroglycan and the sarcoglycans at the sarcolemma of mdx skeletal muscle (Ohlendieck and Campbell, 1991). Because no MT knockout mouse has been generated, the exact function of MTs in skeletal muscle remains unknown. However, the importance of MTs in skeletal muscle biology is illustrated by the muscle weakness and increased levels of serum creatine kinase associated with colchicine toxicity in human patients (Boomershine, 2002; Caglar et al., 2003; Wilbur and Makowsky, 2004; Altman et al., 2007). Therefore, it is possible that derangement of the MT cytoskeleton contributes to some of the phenotypes associated with dystrophin deficiency.

### Materials and methods

#### Mice

Control C57BL/6 and mdx mice were initially obtained from The Jackson Laboratory. The utrn−/− and mdx/utrn−/− mice were provided by D. Lowe (University of Minnesota, Minneapolis, MN). Mdx mice transgenically expressing Dp260 and ΔR4-R23 were provided by J. Chamberlain (University of Washington, Seattle, WA), and the Dp71 line was provided by J. Rafael-Fortney (Ohio State University, Columbus, OH). All animals were housed and treated following guidelines set by the University of Minnesota Institutional Animal Care and Use Committee.

#### Antibodies

The mAbs to α-tubulin (B512), β-tubulin (D66), tyrosinated tubulin (TUB 1-A2), and acetylated tubulin (6-11B-1) were purchased from Sigma-Aldrich. The mAb to α-tubulin (DM1A) was purchased from Abcam. The mAb to dystrophin (Dys2) was purchased from Novocastra. The polyclonal antibody to dystrophin (Rb2) was described previously (Rybakova et al., 1996). Infrared dye-conjugated anti-mouse secondary antibodies were purchased from LI-COR Biosciences.
To analyze the MT lattice in dystrophic animal models, hindlegs of wt and mdx (3, 5, and 8 wk), utrn−/− (8–10 wk), and mdx utrn−/− (3, 5, and 8 wk) mice were skinned, cut as close as possible to the body, and fixed at room temperature for 2 h with 4% para-formaldehyde in phosphate buffer. They were stored in phosphate buffer until the extensor digitorum longus muscle was dissected and separated with fine forceps into mostly single fibers. These were transferred to a 24-well tissue culture plate and incubated with mouse on mouse (MOM)–blocking buffer (Vector Laboratories) for 2 h at room temperature. Blocking buffer and every subsequent buffer for incubation or washing contained 0.04% saponin for permeabilization and 0.05% sodium azide. Fibers were incubated overnight with mouse antitubulin (DM1A, 1:500; or B512, 1:4,000) in MOM diluent, washed three times for 20 min, and stained with 1:500 dilution of Alexa Fluor 488 anti–mouse and Alexa Fluor 568 anti–rabbit secondary antibodies (Invitrogen) in MOM diluent for 2 h at room temperature. After three 20-min washes, one of which contained the nuclear stain Hoechst 33342 (Sigma-Aldrich) at 2 µg/ml, fibers were mounted onto a glass slide in a drop of Vectashield (Vector Laboratories). Confocal images were captured with a 0.63x NA 1.4 oil immersion lens on a TCS SP5 confocal microscope (Leica) in the Light Imaging Section of the National Institute of Arthritis and Musculoskeletal and Skin Diseases. Gain and laser power settings were adjusted to avoid saturation and use the whole linear range of fluorescence intensity. Unless specified, the parameters were adjusted for each new fiber imaged. The raw TIF images were transferred to a computer (Apple, opened in Photoshop [CS2, Adobe], assembled into montages, and adjusted for brightness when needed. The final illustrations give a faithful representation of the collected images.

**Immunofluorescence analysis**

Western blot analysis and quantification

Western blot analysis and quantification from three wt and three mdx skeletal muscle extracts were performed as described previously (Prins et al., 2006). In brief, 25 µg of skeletal muscle extract was subjected to SDS-PAGE and transferred to nitrocellulose membranes, which were washed/blocking in a 5% milk solution in PBS for 1 h. The membranes were incubated overnight with primary antibody at room temperature. The primary antibodies and dilutions used were mAb Dys2 (1:50), mAb B512 (1:250), mAb DM1A (1:250, Sigma-Aldrich), mAb D66 (1:100), and mAb 6-118-1 (1:10,000). Membranes were washed two times for 10 min in 5% milk solution at room temperature, incubated with infrared dye–conjugated secondary antibody (1:10,000) for 30 min at room temperature, and the membranes were washed in a 0.5% Tween solution in PBS two times for 10 min. Western blots were imaged and quantified with an infrared imaging system (Odyssey; LI-COR Biosciences). The Coomassie blue-stained posttransfer gel was analyzed densitometrically using UVP software and served as the loading control.

In vivo tubulin–MT equilibrium assay

The tibialis anterior was dissected, immediately placed in 1 ml of MT stabilization buffer (1% Triton X-100, 50 mM Hepes, 50 mM KCl, 1 mM MgCl2, 1 mM EGTA, 0.75 mM benzamidine, 0.1 mM PMSF, 0.6 µg/ml pepstatin A, 0.5 µg/ml aprotinin, 0.5 µg/ml leupeptin, iodoacetamide, and E64). The extracts were incubated for 1 h at 4°C and centrifuged at 100,000 g for 40 min at 25°C. 1 mM of both GTP and DTT was added to the solubilized fraction of the extract and incubated at 37°C for 5 min. The extract was split into two fractions, one that was incubated on ice for 15 min, and 20 µM taxol was added to the other and incubated at 37°C for 15 min. 300 µl of each fraction was layered onto a cushion buffer (MT buffer plus 40% sucrose) and centrifuged at 100,000 g for 30 min at 25°C. The supernatant was removed, and the pellet fraction was resuspended in a Laemmli sample buffer.

**Protein purification**

A cDNA-encoding Flag-tagged Dp260 (Warner et al., 2002) provided by J. Chamberlain was cloned into pFASTbac to generate a recombinant baculovirus expression vector using previously described methods (Rybakova et al., 2002). Dp260 and dystrophin N-termin-R10 were expressed and purified using the baculovirus expression vector using previously described methods (Rybakova et al., 2002). Dp260 and dystrophin N-termin-R10 were expressed and purified using the baculovirus expression system and anti-Flag M2 affinity chromatography, respectively, as previously described (Rybakova et al., 2002), except the proteins were dialyzed into MT buffer without Triton X-100. Protein concentration was determined using A280 using Nanodrop software with an extinction coefficient of 272,495 M−1 cm−1 for Dp260 and 221,115 M−1 cm−1 for DysNR10 as predicted by the Expert Protein Analysis System proteomics server (Swiss Institute of Bioinformatics).

**MT cosedimentation analysis**

MT cosedimentation analysis was performed as described by the manufacturer’s instructions (Cytoskeleton, Inc.). In brief, increasing amounts of purified protein were added to preformed MTs then centrifuged at 100,000 g for 30 min. The amount of free and bound protein was determined densitometrically from Coomassie blue–stained gels of the supernatant and pelleting in the absence of MTs was subtracted from each data point. The resultant data from three independent experiments were fitted to a hyperbolic binding equation using nonlinear regression analysis on Prism software (GraphPad Software, Inc.).

**Cold-induced depolymerization assay**

Tubulin was incubated to polymerize as described by the manufacturer’s instructions (Cytoskeleton, Inc.) and incubated with 1 µM Dp260. The reactions were incubated at 4°C for 30 min then centrifuged at 100,000 g for 30 min at 4°C. The supernatant and pellet fractions were prepared and quantified as described in the previous paragraph.
