Pericentrin in cellular function and disease

Benedicte Delaval and Stephen J. Doxsey

Pericentrin is an integral component of the centrosome that serves as a multifunctional scaffold for anchoring numerous proteins and protein complexes. Through these interactions, pericentrin contributes to a diversity of fundamental cellular processes. Recent studies link pericentrin to a growing list of human disorders. Studies on pericentrin at the cellular, molecular, and, more recently, organismal level, provide a platform for generating models to elucidate the etiology of these disorders. Although the complexity of phenotypes associated with pericentrin-mediated disorders is somewhat daunting, insights into the cellular basis of disease are beginning to come into focus. In this review, we focus on human conditions associated with loss or elevation of pericentrin and propose cellular and molecular models that might explain them.

Introduction

The centrosome is a cellular organelle composed of centrioles and pericentriolar material (PCM). The PCM is a protein matrix surrounding the centrioles that contains protein complexes required for centrosome-associated functions. A key component of the PCM and centrioles is pericentrin, a large conserved coiled-coil protein (Doxsey et al., 1994; Flory and Davis, 2003; Jurczyk et al., 2004; Martinez-Campos et al., 2004; Miyoshi et al., 2006a).

The centrosome has numerous and complex functions that center primarily around cell cycle regulation and microtubule organization. For example, centrosomes act as platforms for assembling regulatory proteins and pathways (Doxsey et al., 2005) such as progression from G1 to S and from G2 to M, events that require centrosome binding of cyclin E and Chk1, respectively (Krämer et al., 2004; Matsumoto and Maller, 2004; Doxsey et al., 2005). In mitotic cells, centrosomes and associated astral microtubules contribute to mitotic spindle organization (Lüders and Stearns, 2007; O’Connell and Khodjakov, 2007) and mitotic spindle orientation (Rebollo et al., 2007; Rusan and Peifer, 2007; Toyoshima and Nishida, 2007; Yamashita et al., 2007). The latter controls orientation of the cell division plane, which, in turn, controls cell fate determination in many stem cell niches (Rebollo et al., 2007; Rusan and Peifer, 2007; Yamashita et al., 2007). In noncycling cells, the older centriole/basal body serves as the template for assembly of the primary cilium (Rieder et al., 2001).

Through its ability to serve as a multifunctional scaffold for anchoring a wide range of centrosome proteins (Table I), pericentrin is involved in essentially all of the previously described functions. In this review, we will discuss the association between pericentrin function and disease. This protein has been associated with four human disorders. We focus first on primordial dwarfism, which has been directly linked to mutations in the pericentrin gene. Although the connection between pericentrin and other diseases is not as strong, cell and molecular evidence supports a role for pericentrin in human cancer, mental disorders, and ciliopathies. Here, we first discuss each human condition, starting with a brief summary of their salient features and link to pericentrin, then explore the cellular and molecular changes that accompany them. These changes are put in context with studies from multiple experimental systems that provide insight into the mechanisms underpinning these disorders.

Pericentrin in primordial dwarfism

Pericentrin in human and mouse models of dwarfism. Recent studies indicate that PCNT mutations are associated with two rare and complex human autosomal recessive genetic disorders with overlapping features, Majewski/microcephalic osteodysplastic primordial dwarfism type II (MOPDII) and Seckel syndrome (Griffith et al., 2008; Rauch et al., 2008). However, closer evaluation of disease features demonstrated that individuals with Seckel syndrome and PCNT mutations actually belong to the MOPDII spectrum. Moreover, a recent study demonstrates that PCNT mutations are present in all the MOPDII patients examined, confirming the genetic homogeneity of this disorder and suggesting that Seckel patients do not harbor pericentrin mutations (Willems et al., 2009). Individuals with MOPDII present with several features, including extreme proportionate short stature that begins in utero (hence the term primordial dwarfism), with some adults never reaching 20 inches in height (Majewski and Goecke, 2004; Miyoshi et al., 2006a).

In all models, pericentrin is viewed as a multifunctional scaffold protein whose disruption results in loss of pericentrin binding proteins from the centrosome and centrosome dysfunction (Fig. 1).

**Model 1: pericentrin, cell cycle checkpoint defects, and premature mitotic entry.** Through its protein-anchoring function, pericentrin has been implicated in the regulation of cell cycle progression, cell cycle checkpoints, and mitotic entry. Results obtained from MOPDII patient cells and from pericentrin siRNA-treated cultured human cells demonstrate a role for the protein in the ataxia telangiectasia and rad3 related (ATR)-dependent DNA damage checkpoint signaling (Griffith et al., 2008; Tibelius et al., 2009). Components of the ATR pathway localize to the centrosome (Zhang et al., 2007), including the checkpoint kinase 1 (Chk1; Krämer et al., 2004; Löffler et al., 2007). Centrosome-associated Chk1 delays the G2/M transition by inhibiting the Cdc25-dependent activation of cyclin B–Cdk1 complexes (Krämer et al., 2004). In fact, ectopic localization of Chk1 to centrosomes using Chk1 fused to a centrosome targeting polypeptide (PACT domain; Gillingham and Munro, 2000) prevents the transition from G2 to M (Krämer et al., 2004). A more recent study demonstrates that pericentrin is involved in the centrosomal anchoring of Chk1 and its associated G2/M checkpoint arrest pathway (Tibelius et al., 2009). Pericentrin depletion prevents Chk1 recruitment to centrosomes, causing premature mitotic entry, mitotic delay, and cell death. Importantly, defects in the ATR signaling checkpoint pathway are also associated with other disorders such as microcephaly, a well-documented characteristic of primordial dwarfism, thus

1982; Majewski et al., 1982; Hall et al., 2004), small brain size relative to body size (microcephaly), and bony dysplasia (Majewski and Goecke, 1982; Majewski et al., 1982; Hall et al., 2004; Willems et al., 2009).

Preliminary results suggest that disruption of the *PCNT* gene in mice (Miyoshi et al., 2009; unpublished data; Akbarian, S., C. Lo, and G. Zheng, personal communication) may provide a good model for understanding features of human primordial dwarfism. Disruption of the gene by insertional mutagenesis using gene trap technology causes reduction in the total cellularity of the growing embryo and adult organism. Several cell biological models have been proposed to explain this phenomenon and how it might contribute to the disease (Delaval and Doxsey, 2008; Griffith et al., 2008; Rauch et al., 2008). In all models, pericentrin is viewed as a
Model 2: pericentrin, microtubules, and mitotic defects. A large body of evidence supports a role for pericentrin in microtubule nucleation and spindle organization. Pericentrin homologues in a variety of organisms, including the budding yeast *Saccharomyces cerevisiae* (spc110p/ Nuf1p; Knop and Schiebel, 1997; Flory et al., 2000), the fission yeast *Schizosaccharomyces pombe* (Pep1p; Flory et al., 2002), the filamentous fungus *Aspergillus nidulans* (Flory et al., 2002), and *Drosophila* (d-plp; Martinez-Campos et al., 2004), localize to centrosomes or the equivalent structure where they anchor proteins involved in microtubule nucleation and organization (Kilmartin and Goh, 1996; Sundberg et al., 1996; Flory et al., 2002).
organize mitotic spindles, and perform mitotic functions (Doxsey et al., 1994; Sundberg et al., 1996; Sundberg and Davis, 1997; Flory et al., 2002; Martinez-Campos et al., 2004). For example, D-plp is required for efficient recruitment of PCM components to centrosomes (Martinez-Campos et al., 2004). Spc110p has affinity for the GCP2/3 orthologues in yeast (spc97p and spc98p) and anchors γ-tubulin complexes at spindle poles (Knop and Schiebel, 1997), thus allowing proper mitotic spindle assembly (Sundberg et al., 1996; Sundberg and Davis, 1997). PCP1p also functions in spindle pole body assembly and microtubule nucleation (Flory et al., 2002).

In humans, the microtubule-nucleating function of pericentrin also requires its recruitment to the PCM, which is accomplished through a microtubule-based transport mechanism involving cytoplasmic dynein (Young et al., 2000). Centrosomal recruitment of pericentrin and other centrosome proteins including the pericentrin-binding protein γ-tubulin, reaches a maximum at metaphase (Dichtenberg et al., 1998) in a process called “centrosome maturation” (Glover, 2005; Bettencourt-Dias and Glover, 2007). This process is critical for centrosome-based astral and spindle microtubule nucleation in mitosis. Pericentrin depletion by RNAi disrupts microtubule nucleation from mitotic centrosomes, most likely through mislocalization of the microtubule-nucleating protein γ-tubulin from spindle poles, a phenotype that seems to be mitosis specific because interphase microtubules appear largely intact (Doxsey et al., 1994; Li et al., 2001; Dammermann and Merdes, 2002; Zimmerman et al., 2004). This mitotic function of pericentrin was confirmed and extended by the recent observation that PLK1-dependent recruitment of γ-tubulin complexes to mitotic centrosomes/spindle poles requires pericentrin (Haren et al., 2009) and dynein-dependent microtubule transport. These molecular functions of pericentrin are a likely explanation for the decrease in γ-tubulin from spindle poles observed in cells from individuals with primordial dwarfism (Griffith et al., 2008). Consistent with the previously reported role for pericentrin in spindle organization in cultures of human cells (Purohit et al., 1999; Zimmerman et al., 2004), mitotic defects are observed in cells from MOPDII individuals lacking pericentrin and include disorganized mitotic spindles, chromosome misalignment, premature sister chromatid separation, and aneuploidy (Rauch et al., 2008).

Collectively, these observations suggest a role for spindle dysfunction in primordial dwarfism. In this model (Fig. 1), pericentrin disruption would lead to mislocalization of proteins involved in microtubule nucleation/orientation from spindle poles. This would result in mitotic spindle defects, chromosome missegregation and mitotic failure, which could lead to cell cycle arrest and/or cell death (Rauch et al., 2008), thus contributing to the global loss of cellularity seen in MOPDII.

Model 3: pericentrin, astral microtubules, and spindle orientation: Evidence from the literature and ongoing experiments support a role for spindle misorientation as a contributor to MOPDII. The first clue to this idea comes from studies linking microcephaly to spindle misorientation and abnormal stem cell division. Three centrosome genes have been implicated in this disorder: ASPM, Cdk5RAP2/centrosomin, and CENPJ/SAS-4. All have well-characterized functions including astral microtubule nucleation, spindle organization, and/or orientation (do Carmo Avides and Glover, 1999; Megraw et al., 2001; Basto et al., 2006). Recent studies on these centrosome genes suggest that microcephaly results from the inability to self-renew neuronal stem cells. This appears to occur through misorientation of mitotic spindles, leading to asymmetric divisions that produce differentiating cells instead of stem cells, thus depleting the total cellularity of the stem cell compartment (Bond and Woods, 2006). This would lead to a reduction in the total number of neurons in the brain and a reduced brain size. These results from studies on microcephaly provide a testable model for the mechanism of pericentrin in primordial dwarfism. PCNT mutations could cause short stature and small brain size in primordial dwarfishisms through an imbalance in symmetric versus asymmetric cell divisions resulting from spindle misorientation in all organs of the body.

Correct orientation of mitotic spindles and, subsequently, the plane of cell division are achieved through proper nucleation and organization of astral microtubules that emanate from spindle poles (Fig. 1; Toyoshima and Nishida, 2007). Loss of centrosomal γ-tubulin and astral microtubules is observed upon RNAi-mediated knockdown of pericentrin in cultured human cells (Zimmerman et al., 2004), which suggests a role for pericentrin in spindle orientation. In addition, pericentrin overexpression blocks proper mitotic spindle positioning within cells (Purohit et al., 1999).

Work in Drosophila supports a role for pericentrin in microtubule organization and mitosis. D-plp mutant embryos are defective for timely recruitment of PCM components to centrosomes (maturation) and show a reduction in centrosomal microtubules (Martinez-Campos et al., 2004). However, in this system, these defects cause relatively subtle defects in the organization of spindle poles and mitotic spindles (Martinez-Campos et al., 2004). This might be expected because, remarkably, flies completely lacking centrosomes can still complete cell division and develop normally (Basto et al., 2006). Rather than dying from mitotic dysfunction, adults in both cases die from cilia defects. However, it is important to note that flies lacking centrosomes exhibit disorganized astral microtubules and misoriented spindles, which might be expected to adversely affect the balance of symmetric and asymmetric divisions in stem cell compartments (Basto et al., 2006). However, in D-plp mutants, this detail was not examined. Thus, it is possible that D-plp disruption induces more subtle defects in spindles such as changes in spindle orientation. These would induce more moderate yet uncharacterized mitotic defects that could be manifested in specific tissues where proper spindle orientation is important.

In agreement with a model in which pericentrin is required for correct spindle orientation, fibroblasts isolated from PCNT knockout mice show a significant increase in cells with disrupted astral microtubules and misoriented spindles (Fig. 2; unpublished data; Zheng, G., personal communication). Spindle misorientation is shown by an increase in the angle formed by the pole-to-pole spindle vector and the cell–substrate adhesion plane in pericentrin knockout compared with wild-type...
functions, suggested by the diversity of pericentrin interacting partners (Table I), contribute to disease etiology.

Pericentrin in human cancer

Centrosome abnormalities and chromosome instability in cancer. Aberrant centrosome numbers were first described in human cancer cells by T. Boveri (1929). Centrosome defects were rediscovered in human carcinomas and tumor-derived cell lines in 1998 using specific markers (Lingle et al., 1998; Pihan et al., 1998) and have now become a hallmark of most solid tumors and some hematological malignancies. Aberrant centrosomes and associated abnormal mitotic spindles show a strong correlation with chromosome instability, another common feature of cancer cells (Lengauer et al., 1997; Pihan et al., 1998, 2003). Perhaps most important is the recent use of network modeling that directly links breast cancer susceptibility to centrosome defects (Pujana et al., 2007).

Pericentrin in solid tumors and hematological malignancies in humans. Centrosomal abnormalities in solid tumors are accompanied by increased pericentrin levels and defects in pericentrin organization, demonstrating the utility of pericentrin as a potential marker for centrosome defects in cancer and implicating the protein in cancer progression (Pihan et al., 1998). Consistent with these observations are data from expression profiling showing that PCNT and other centrosome-associated genes are highly expressed in acute myeloid leukemia (AML). Higher levels of pericentrin also correlate with aneuploidy and centrosome aberration levels in AML (Neben et al., 2004; Krämer et al., 2005). In mantle cell lymphoma, pericentrin is part of an expression signature identifying genes.

Figure 2. Fibroblasts from PCNT knockout mice show loss of astral microtubules and spindle misorientation. Top (a and c) and side (b and d) views of three-dimensional reconstructed immunofluorescence images of mitotic spindle stained for α-tubulin (green), γ-tubulin (red), and kinetochore (CREST, blue). Mitotic spindles are misoriented in PCNT−/− (b) versus wild-type cells (d). α, metaphase spindle angle relative to the bottom of the dish. Astral microtubules in the wild-type cell (a, arrow) are lost in PCNT−/− cells (b, arrow with broken line). MEF, mouse embryonic fibroblast. Images provided by S. Doxsey and G. Zheng (University of Massachusetts Medical School, Worcester MA).
In agreement with this model, fibroblasts isolated from pericentrin-overexpressing mice are aneuploid and show supernumerary centrosomes, multipolar spindles, and bipolar spindles with clustered centrosomes (Fig. 3; Krämer, A., personal communication). A likely mechanism for the formation of supernumerary centrosomes and abnormal mitotic spindles after pericentrin disruption is cytokinesis failure, resulting in twice the number of centrosomes and chromosomes (Chen et al., 2004). They also show an increased mitotic index and decreased proliferation, potentially resulting from the observed mitotic dysfunction. Centrosome clustering may allow cancer cells with multiple centrosomes to undergo relatively normal cell divisions, but, ultimately, it is likely to lead to genetic instability, a known contributor of cancer (Quintyne et al., 2005; Rebacz et al., 2007; Kwon et al., 2008). Like fibroblasts from \textit{PCNT} transgenic mice, bone marrow cells are aneuploid and also show nuclear abnormalities and increased apoptosis (Krämer, A., personal communication), which suggests that hematopoietic progenitor cells fail to undergo productive divisions and ultimately die as a result of mitotic defects and aneuploidy.

\textbf{Proposed model for pericentrin function in cancer.} These results support our previously proposed model to explain how disruption of pericentrin function would induce tumor formation (Fig. 1; Pihan et al., 2001; Pihan and Doxsey, 2003). Increased levels of pericentrin would cause alterations in centrosome number, structure, and function. This, in turn, would alter mitotic spindle organization and function, leading to chromosome missegregation. The resulting losses and gains of chromosomes after cell division would generate aneuploidy or chromosomal instability. Cells that accumulate chromosomes with activated oncogenes or lose chromosomes with inactivated tumor suppressors (i.e., changes in gene dosage) would survive by Darwinian selection based on their ability to outlive or outgrow their counterparts.
Pericentrin and mental disorders

Pericentrin in bipolar disorder (BPD), major depressive disorder (MDD), and schizophrenia. Changes in pericentrin levels are associated with mental disorders. Recent studies reveal elevated pericentrin expression in the postmortem brain and peripheral blood lymphocytes in BPD and in patients with MDD (Anitha et al., 2008). More recent studies suggest a genetic linkage between the PCNT gene and MDD. Genotyping of single-nucleotide polymorphisms (SNPs) in the PCNT gene reveals significant differences in allelic frequencies between patients with MDD and controls for two SNPs (Numata et al., 2009). Furthermore, SNP and haplotype analysis reveals a significant association with schizophrenia (Anitha et al., 2009). Collectively, the data from these studies suggest that pericentrin might play a role in the pathophysiology of BPD, MDD, and schizophrenia, and could be a generalized genetic risk factor for psychiatric illnesses that also influence cognition in healthy subjects (Porteous et al., 2006).

Proposed models for pericentrin in mental disorders. Clues to the role of pericentrin in mental disorders come from its interaction with the protein product of disrupted in schizophrenia 1 (DISC1; Miyoshi et al., 2004; Shimizu et al., 2008), a gene that is a known genetic risk factor for mental disorders including schizophrenia, MDD, and BPD. DISC1 is anchored to centrosomes by pericentrin (Miyoshi et al., 2004). Expression of the DISC1 domain that binds pericentrin releases DISC1 from centrosomes and disrupts microtubules (Shimizu et al., 2008). This suggests that the DISC1–pericentrin interaction might be important for microtubule organization and that disruption of this interaction could contribute to mental disorders. In addition to its microtubule function, DISC1 associates with several proteins involved in processes essential for neuronal function, including neuronal migration, neurite outgrowth, cytoskeletal modulation, and signal transduction (Hennah et al., 2006). This suggests that pericentrin disruption could disrupt any of these processes. Three exploratory models could explain how microtubule defects in pericentrin-disrupted cells could contribute to mental disorders (Fig. 1).

Model 1: PCNT and neurite outgrowth and interconnectivity. First (Fig. 1), disruption of microtubule integrity in neurons could affect neurite outgrowth and interconnectivity during development (Matsuzaki and Tohyama, 2007). Microtubules play an essential role both in formation and maintenance of neuronal processes including axonal outgrowth and fasciculation, and dendritic arborization. It is worth noting that the pericentrin-binding region of DISC1 overlaps with the region interacting with FEZ1 (Miyoshi et al., 2004), a schizophrenia susceptibility gene that plays a vital role in axonal outgrowth and fasciculation (Yamada et al., 2004). These three proteins may cooperate in establishing and maintaining axons and dendrites.

Model 2: PCNT and cell migration. Second (Fig. 1), disruption of the centrosome and associated microtubules could affect cell migration (Higginbotham and Gleeson, 2007). An increasing number of psychiatric susceptibility genes regulate neuronal migration, which is important for development and organization of the brain. This includes PCM1 (Gurling et al., 2006), a pericentrin interacting protein (Li et al., 2001) that is also a member of the DISC1 interactome (Kamiya et al., 2008). Suppression of PCM1 in the developing cerebral cortex leads to neuronal migration defects (Kamiya et al., 2008). Therefore, through its interaction with PCM1 and DISC1, pericentrin could affect neuronal migration.

Model 3: PCNT and spindle orientation. Third (Fig. 1), disruption of mitotic astral microtubules in pericentrin-depleted cells (Zimmerman et al., 2004) is likely to contribute to aberrant spindle orientation (see “Pericentrin in primordial dwarfism”) and consequently could disrupt the asymmetric segregation and inheritance of centrosomes in neuronal stem/progenitor cells. This could decrease neuronal precursor self-renewal and disrupt cellular balances affecting neuron number and tissue organization. In fact, disruption of asymmetric inheritance of centrosomes has recently been shown to lead to premature depletion of progenitors in the developing mammalian neocortex (Wang et al., 2009).

Additional studies are required to directly demonstrate a role for pericentrin in these disorders and test whether pericentrin, DISC1, PCM1, and FEZ1 function together in the same pathway or individually to contribute to cortical development and the pathogenesis of neurodevelopmental disorders.

Pericentrin in ciliopathies

Disruption of cilia formation or function has long been associated with ciliopathies (Hildebrandt and Otto, 2005). PCNT has not been directly linked to ciliopathies in humans, but recent evidence demonstrates that disruption of the gene contributes to ciliopathy-associated phenotypes in model organisms, including Drosophila and mice (Martinez-Campos et al., 2004; Miyoshi et al., 2009). Pericentrin in mouse and fly models of ciliopathy. Pericentrin localizes to the base of primary cilia in several mouse embryonic tissues, which suggests a role for the protein in cilia formation (Miyoshi et al., 2006b). In fact, hypomorphic mutations in the mouse PCNT gene lead to compromised assembly of the olfactory cilia of chemo sensory neurons in the nasal olfactory epithelium and reduced olfactory performance (Miyoshi et al., 2009). In vivo studies in Drosophila also demonstrate a role for the pericentrin-like protein (d-plp) in cilia formation. d-plp mutant flies are severely uncoordinated, a phenotype associated with malformed sensory cilia that results in disturbed neuronal function and that is consistent with the mouse model. In contrast to the mouse model, d-plp mutant flies are also defective for the formation of motile cilia and flagella (Martinez-Campos et al., 2004). One possible explanation for the difference in results in the two model organisms is the hypomorphic mutation in the mouse and presumably higher protein levels that may allow normal function of motile cilia and flagella.

Pericentrin and cilia formation in cultured cells. Studies in cultured cells provide additional insight into the role of pericentrin in cilia assembly and function. In non-cycling cells, depletion of pericentrin by RNAi shows a dramatic reduction in the assembly of primary cilia (Jurczuk et al., 2004; Graser et al., 2007; Mikule et al., 2007). Mechanistically,
pericentrin could function in cilia assembly through its association with known cilia proteins such as intraflagellar transport (IFT) proteins and polycystin-2 (Jurczyk et al., 2004). Along these lines, pericentrin showed codependency with IFT proteins in localization to centrosomes (Jurczyk et al., 2004).

**Proposed models for pericentrin in ciliopathy and associated cyst formation.** Even without direct evidence for a role for pericentrin in ciliopathies in humans, observations from a pericentrin knockout mice model (unpublished data; Lo, C., and G. Zheng, personal communication) associate the loss of pericentrin with the formation of cysts in the kidney, a phenotype typically associated with ciliopathy.

**Model 1: PCNT and cilia formation.** Cilia disruption has long been associated with cystic kidneys (Hildebrandt and Otto, 2005). This suggests a model (Fig. 1) in which disruption of pericentrin would reduce recruitment of protein complexes involved in primary cilia formation to the basal bodies at the base of the primary cilium (centrosome) and consequently lead to loss of cilia and cyst formation.

**Model 2: PCNT and spindle orientation.** An alternative model (Fig. 1) for cyst formation in ciliopathies would be misorientation of cell division. Recent work in several mouse models of ciliopathy suggests that misoriented cell division contributes to ciliopathies and cyst formation (Fischer et al., 2006; Jonassen et al., 2008; Patel et al., 2008; Saburi et al., 2008). In these studies, cell division in the epithelial layer is oriented perpendicular to the longitudinal dimension, thus increasing the diameter of ducts. Preliminary observations suggest that pericentrin knockout mice exhibit misoriented cell divisions (unpublished data; Zheng, G., personal communication). This finding, together with the role of pericentrin in spindle positioning previously described (see Pericentrin in primordial dwarfism), suggests that the protein might also contribute to cyst formation in mice through spindle and cell division misorientation.

**Concluding remarks**

In this review, we discuss diverse human disorders linked to pericentrin by genetics (MOPDII), protein level changes, or association with results from experimental systems. Where possible, we detail and integrate the cell and molecular changes that characterize both human conditions and experimental models of these disorders. What emerges from this review of published and ongoing work (at an early stage in our understanding of the etiology of pericentrin-associated disorders) is a complex picture potentially involving disruption of multiple pathways either alone or together to generate phenotypes likely to contribute to disease etiology (Fig. 1).

A unifying theme underlying the diverse deficiencies associated with pericentrin-associated disorders is loss of microtubule integrity resulting from compromised centrosome function. As a multifunctional scaffold protein, pericentrin binds proteins of diverse cellular pathways. In this model, pericentrin disruption would mislocalize proteins essential for microtubule integrity (β-tubulin and DISC1) or cilia proteins (IFT) from centrosomes/spindle poles/basal bodies. The resulting loss of microtubule integrity could explain the defects observed in interphase/G0 (e.g., cilia, neuronal outgrowth, and motility) and mitosis (spindle disorganization and misorientation). Mitotic dysfunction is the feature that appears in all four disorders either through spindle disorganization leading to cell death or aneuploidy, or through spindle misorientation leading to depletion of stem cells. A second potential pathway cocontributing to disease phenotypes is disruption of centrosome proteins involved in cell cycle regulation (Chk1).

The proposed theme that links all disorders does not explain the lack of overlap of some phenotypes. For example, why is cancer not a feature of MOPDII if multipolar spindle misorientation is a common phenotype to explain both dwarfism and cancer? Future studies are required to further test this model and others to gain a full understanding of the cellular and molecular underpinnings of the disorders associated with mutated, deleted, or elevated levels of pericentrin in human disease.

We are particularly grateful to A. Kramer, C. Lo, S. Akbarian, J. Raff, T. Davis, and W. Zimmerman for thoughtful discussions on this manuscript. We also would like to thank A. Kramer, C. Lo, and, from S. Doxsey’s laboratory, G. Zheng and S. Redick for sharing unpublished results.

This work was supported by funding from the National Institutes of Health (GM051994-14) to S.J. Doxsey and the Polycystic Kidney Disease Foundation to B. Delaval.
