Intraflagellar transport (IFT) was first described in the flagella of *Chlamydomonas* (Kozminski et al., 1993) and has since been proven to be a conserved process in a variety of motile and non-motile cilia in eukaryotic organisms (Sloboda, 2005). IFT comprises the bidirectional transport of IFT particles containing ciliary or flagellar cargo along the outer doublet microtubules of the axoneme (Rosenbaum and Witman, 2002). These processes ensure the assembly and the molecular turnover of ciliary components (Qin et al., 2004) but also take part in signaling processes generated in the cilium (Wang et al., 2006). Genetic evidence indicates that kinesin-II family members serve as anterograde transport motors in IFT (Kozminski et al., 1995; Cole et al., 1998; Snow et al., 2004), whereas the cytoplasmic dynein 2/1b mediates IFT in the retrograde direction (Pazour et al., 1998, 1999; Signor et al., 1999a). Biochemical analyses revealed that IFT particles are composed of IFT proteins organized into two complexes, A and B (Cole et al., 1998; Cole, 2003). The sequences of IFT proteins are highly conserved between species, and mutations in these genes disturb ciliary assembly in all organisms tested (Cole et al., 1998; Murcia et al., 2000; Pazour et al., 2002; Tsujikawa and Malicki, 2004; Krock and Perkins, 2008; Omori et al., 2008). Nevertheless, the specific functions of the individual IFT proteins in IFT as well as their subcellular and subcompartmental localization in cilia remain to be elucidated (Sloboda, 2005). Interestingly, there is growing evidence for a role of IFT proteins in processes not associated with cilia (Pazour et al., 2002; Follit et al., 2006; Jékely and Arendt, 2006; Finetti et al., 2009; Baldari and Rosenbaum, 2010).

Over the last decade, IFT has been studied intensively in sensory cilia, including photoreceptor cell outer segments (OSs) in the vertebrate retina (e.g., Beech et al., 1996; Pazour et al., 2002; Baker et al., 2003; Insinna et al., 2008, 2009; Krock and Perkins, 2008; Luby-Pheelps et al., 2008). Vertebrate photoreceptors are highly polarized sensory neurons consisting of morphologically and functionally distinct cellular compartments. A short axon projects from the cell body of the photoreceptor to form synaptic contact with secondary retinal neurons (bipolar and horizontal cells), and at the opposite pole, a short dendrite is differentiated into the inner segment (IS) and the light-sensitive OS (Fig. 1; Besharse and Horst, 1990; Roepman and Wolfrum, 2007). The OS is similar to other sensory cilia (Insinna and Besharse, 2008) but, in addition, contains specialized cytoplasmic transport, where they are associated with transport vesicles. IFT20 is not in the IFT core complex in photoreceptor cilia but accompanies Golgi-based sorting and vesicle trafficking of ciliary cargo. Moreover, we identify a nonciliary IFT system containing a subset of IFT proteins in dendrites of retinal neurons. Collectively, we provide evidence to implicate the differential composition of IFT systems in cells with and without primary cilia, thereby supporting new functions for IFT beyond its well-established role in cilia.

**The assembly and maintenance of cilia require intraflagellar transport (IFT), a process mediated by molecular motors and IFT particles. Although IFT is a focus of current intense research, the spatial distribution of individual IFT proteins remains elusive. In this study, we analyzed the subcellular localization of IFT proteins in retinal cells by high resolution immunofluorescence and immunoelectron microscopy. We report that IFT proteins are differentially localized in subcompartments of photoreceptor cilia and in defined periciliary target domains for molecular transport, where they are associated with transport vesicles. IFT20 is not in the IFT core complex in photoreceptor cilia but accompanies Golgi-based sorting and vesicle trafficking of ciliary cargo. Moreover, we identify a nonciliary IFT system containing a subset of IFT proteins in dendrites of retinal neurons. Collectively, we provide evidence to implicate the differential composition of IFT systems in cells with and without primary cilia, thereby supporting new functions for IFT beyond its well-established role in cilia.**

---

**Introduction**

Intraflagellar transport (IFT) was first described in the flagella of *Chlamydomonas* (Kozminski et al., 1993) and has since been proven to be a conserved process in a variety of motile and non-motile cilia in eukaryotic organisms (Sloboda, 2005). IFT comprises the bidirectional transport of IFT particles containing ciliary or flagellar cargo along the outer doublet microtubules of the axoneme (Rosenbaum and Witman, 2002). These processes ensure the assembly and the molecular turnover of ciliary components (Qin et al., 2004) but also take part in signaling processes generated in the cilium (Wang et al., 2006). Genetic evidence indicates that kinesin-II family members serve as anterograde transport motors in IFT (Kozminski et al., 1995; Cole et al., 1998; Snow et al., 2004), whereas the cytoplasmic dynein 2/1b mediates IFT in the retrograde direction (Pazour et al., 1998, 1999; Signor et al., 1999a). Biochemical analyses revealed that IFT particles are composed of IFT proteins organized into two complexes, A and B (Cole et al., 1998; Cole, 2003). The sequences of IFT proteins are highly conserved between species, and mutations in these genes disturb ciliary assembly in all organisms tested (Cole et al., 1998; Murcia et al., 2000; Pazour et al., 2002; Tsujikawa and Malicki, 2004; Krock and Perkins, 2008; Omori et al., 2008). Nevertheless, the specific functions of the individual IFT proteins in IFT as well as their subcellular and subcompartmental localization in cilia remain to be elucidated (Sloboda, 2005). Interestingly, there is growing evidence for a role of IFT proteins in processes not associated with cilia (Pazour et al., 2002; Follit et al., 2006; Jékely and Arendt, 2006; Finetti et al., 2009; Baldari and Rosenbaum, 2010).

Over the last decade, IFT has been studied intensively in sensory cilia, including photoreceptor cell outer segments (OSs) in the vertebrate retina (e.g., Beech et al., 1996; Pazour et al., 2002; Baker et al., 2003; Insinna et al., 2008, 2009; Krock and Perkins, 2008; Luby-Pheelps et al., 2008). Vertebrate photoreceptors are highly polarized sensory neurons consisting of morphologically and functionally distinct cellular compartments. A short axon projects from the cell body of the photoreceptor to form synaptic contact with secondary retinal neurons (bipolar and horizontal cells), and at the opposite pole, a short dendrite is differentiated into the inner segment (IS) and the light-sensitive OS (Fig. 1; Besharse and Horst, 1990; Roepman and Wolfrum, 2007). The OS is similar to other sensory cilia (Insinna and Besharse, 2008) but, in addition, contains specialized cytoplasmic transport, where they are associated with transport vesicles. IFT20 is not in the IFT core complex in photoreceptor cilia but accompanies Golgi-based sorting and vesicle trafficking of ciliary cargo. Moreover, we identify a nonciliary IFT system containing a subset of IFT proteins in dendrites of retinal neurons. Collectively, we provide evidence to implicate the differential composition of IFT systems in cells with and without primary cilia, thereby supporting new functions for IFT beyond its well-established role in cilia.
massive vectorial transport of all OS components from the site of their biogenesis in the photoreceptor IS to the base of the OS, the site of disk neogenesis. On its route to the OS, cargo has to be reloaded from IS transport carriers to ciliary transport systems in a specialized compartment of the apical IS (Papermaster, 2002; Roepman and Wolfrum, 2007; Maerker et al., 2008). In addition to the unidirectional constitutive translocations of OS flattened disk-like membranes, where all components of the visual transduction cascade are arranged (Yau and Hardie, 2009). These phototransductive membranes are continually renewed throughout lifetime; newly synthesized membranes are added at the base of the OS, whereas aged disks at the apex are phagocytosed by cells of the retinal pigment epithelium (RPE; Young, 1976). This high membrane turnover implies an efficient and massive vectorial transport of all OS components from the site of their biogenesis in the photoreceptor IS to the base of the OS, the site of disk neogenesis. On its route to the OS, cargo has to be reloaded from IS transport carriers to ciliary transport systems in a specialized compartment of the apical IS (Papermaster, 2002; Roepman and Wolfrum, 2007; Maerker et al., 2008). In addition to the unidirectional constitutive translocations of OS
molecules, light-dependent bidirectional movement of molecules across the connecting cilium (CC) contributes to the long range light adaptation of rod photoreceptor cells (Calvert et al., 2006). Structural and molecular characteristics qualify the CC as the equivalent of the transition zone localized between the basal body (BB) and the axoneme in proteotypic cilia (Fig. 1 A; Besharse and Horst, 1990; Roepman and Wolfrum, 2007; Insinna and Besharse, 2008). Some microtubules of the CC extend throughout almost the entire length of the OS, where they mediate protein trafficking within the OS (Liu et al., 2002; Reidel et al., 2008).

IFT has been proposed as an essential transport mechanism in photoreceptor cells (Rosenbaum et al., 1999), and its critical importance has been demonstrated subsequently (Pazour et al., 2002; Tsujikawa and Malicki, 2004; Krock and Perkins, 2008). As in other ciliated and flagellated cells, the mode of the IFT operation and the assignment of specific functions to individual IFT proteins are still lacking in photoreceptor cells (Baker et al., 2004; Hou et al., 2007; Bhowmick et al., 2009). A systematic analysis of the subcellular distribution of IFT proteins in photoreceptor cells will provide important insights into the roles of IFT proteins unique for specialized photoreceptor cilia but also into more general processes associated with IFT proteins common to all cilia and flagella. So far, studies on the distribution of IFT proteins in photoreceptor cells were limited to a few immunofluorescence analyses (Pazour et al., 2002; Tsujikawa and Malicki, 2004; Krock and Perkins, 2008) and to a preliminary electron microscopic study on IFT88 (Luby-Phelps et al., 2008), which collectively provided only limited insight into the spatial distribution of IFT proteins.

In this study, we used a combination of high resolution immunofluorescence and immunoelectron microscopy for the analyses of the spatial distribution of IFT proteins in retinal neurons. Our data reveal that IFT proteins are differentially localized in subciliary compartments but also present in nonciliary compartments of photoreceptor cells. Furthermore, the localization of IFT proteins in dendritic processes of nonciliated neurons indicates that IFT protein complexes operate in nonciliated cells and may participate in intracellular vesicle trafficking in eukaryotic cells in general.

Results

Although substantial biochemical and genetic efforts have been undertaken and genetic evidence indicates important roles of each IFT particle protein in the development and maintenance of cilia, the functions of the individual IFT molecules remained largely elusive (Sloboda, 2005). This is partly because of the insufficient knowledge concerning the subcellular localization of the IFT proteins. In this study, we have systematically analyzed the expression and subcellular localization of four different IFT complex B proteins, IFT20, -52, -57, and -88, as well as the complex A protein IFT140 in the mouse retina.

Expression of IFT proteins in the mammalian retina

IFT protein expression was accessed by Western blots using previously characterized affinity-purified polyclonal antibodies raised to murine IFT proteins (Pazour et al., 2002; Baker et al., 2003; Folli et al., 2006). These experiments verified the expression of all five IFT proteins in the murine retina (Fig. S1, A and B). The antibodies to four IFT proteins each recognized a single band of expected size in retinal protein extracts, which implied that these antibodies are monospecific. Only anti-IFT52 detected a second band with a slightly lower molecular weight in retinal extracts, which was not observed in analyses of testis samples (Fig. S1, A and C). This band might be caused by a splice variant of IFT52, which is expressed in the retina but is absent in testis.

The retina is composed of well-defined layers consisting of specific cell types or even at subcellular compartments of retinal cells (Fig. 1). This spatial organization makes it relatively easy to determine the subcellular localization of proteins in retinal sections, even under light microscopy. To determine the subcellular distribution of IFT proteins in the retina, cryosections of mouse eye were analyzed by indirect immunofluorescence. As expected from previous studies (Pazour et al., 2002; Krock and Perkins, 2008), all IFT molecules were most abundant in the photoreceptor layer of the retina (Fig. 1). Weak immunoreactivity for IFT88 was also found in the outer nuclear layer (ONL), where the perikarya of the photoreceptor cells are located (Fig. 1 G), and for all IFT molecules in the inner nuclear layer (INL), where the perikarya of the secondary retinal neurons are found (Fig. 1, D–H). Immunostaining for IFT20, -52, and -57 was also observed in the outer plexiform layer (OPL), which contains the presynaptic terminals of photoreceptor cells connected to the postsynaptic terminals of the dendritic processes in secondary retinal neurons, namely bipolar and horizontal cells (Fig. 1, D–F). In addition, IFT20 was expressed in the cells of the RPE and in the ganglion cell layer (Fig. S2 A). The localization of these five IFT proteins in the mouse retina (Fig. 1 I) was identical to that found by indirect immunofluorescence in human and bovine retinas (Fig. S3). To exclude epitope masking by fixation (Folli et al., 2006), we also performed immunocytochemistry on methanol-fixed cryosections and observed no changes in immunostaining (Fig. S4).

Differential subciliary localization of IFT proteins in the photoreceptor cilium

To elucidate the subciliary localization of IFT proteins in the photoreceptor cell layer of the mouse retina, cryosections were analyzed by double labeling with antibodies against IFT proteins and markers of subciliary compartments. Double labeling with anti–centrin-3, a marker for the CC, the BB, and the adjacent centriole (Trojan et al., 2008), and with antibodies to IFT proteins allowed us to determine the spatial localization of IFT proteins in the photoreceptor ciliary apparatus (Fig. 2).

High resolution immunofluorescence imaging of double labeled specimens revealed different subciliary localization of the IFT proteins, as shown in Fig. 2. Double labeling experiments revealed that IFT52, -57, -88, and -140 were concentrated on the tip of the CC in the OS base (Fig. 2, B’–E’). IFT88 and -140 were also detected in the axoneme, which extended further into the distal part of the OS of photoreceptors (Fig. 2, D’ and E’). Latter axonemal localization of these IFT proteins was confirmed...
by double labeling with an antibody to RP1, a molecular marker for the photoreceptor axoneme (Fig. S2 C; Liu et al., 2002). Weaker staining of IFT52, -57, -88, and -140 was present along the shaft of the CC (Fig. 2, B’–E’). Strong immunoreactivity for IFT52, -57, and -88 was also observed in the basal part of the CC, whereas the anti-IFT140 immunofluorescence was less...
intense in this area (Fig. 2, B’–E’). In contrast to the other IFT proteins analyzed, IFT20 was only detected in the basal part of the CC and at the distal region of the adjacent centriole (Fig. 2 A’). We also detected weak immunofluorescence of IFT52 at the centriole (Fig. 2 B’).

To pinpoint the subcellular localization of the IFT molecules in photoreceptor cells more precisely, we performed immunoelectron microscopy, accessing our recently introduced preembedding labeling technique (Maerker et al., 2008; Sedmak et al., 2009). Our electron microscopy data confirmed the subciliary localization of the IFT proteins in photoreceptor cells, as demonstrated by immunofluorescence. Furthermore, they provided deeper insights into the spatial distribution of IFT proteins in retinal cells. Exploiting the high resolution of the electron microscope, we observed IFT52, -57, -88, and -140 labeling in the OS base and in the basal part of the photoreceptor CC (Fig. 3, A and E; Fig. 4, A and D; and Fig. 5, A and D). In addition, IFT57, -88, and -140 were routinely detected alongside the microtubule doublets in the shaft of the CC (Fig. 3, D and G; and Fig. 4, A and D), whereas IFT52 was concentrated in patches associated with the ciliary membrane and microtubule doublets (Fig. 5 A). The IFT88 and -140 staining extended along the axoneme further into the photoreceptor OS (Figs. 3 E and 4 A). The intense labeling of IFT88 at the axoneme of the OS (Fig. 3 H) is consistent with recently published data on GFP-tagged IFT88 in transgenic frogs (Luby-Phelps et al., 2008). At the base of the CC, IFT52, -57, -88, and -140 were consistently associated with the BB (Fig. 3, A, E, and I; Fig. 4, A and C; and Fig. 5 D). In addition, IFT57, -88, and -140 were regularly concentrated beneath the periciliary groove (Fig. 3, A, E, and I; and Fig. 4 A), in the region where the IFT particle assembly has been suggested in Chlamydomonas (Deane et al., 2001). Furthermore, clusters of immunolabeling by antibodies to IFT57, -88, and -140 were routinely observed at vesicle-like structures in the periphery of the basal bodies and of the adjacent centriole in the cytoplasm of the photoreceptor IS (Fig. 3, A, C, and I; and Fig. 4 C). To emphasize vesicles and vesicle-like structures hardly recognizable in the low contrast images of the present immunoelectron microscopy analysis, we provide images at higher magnification of selected regions with and without colorized vesicles (Fig. 3, C, C’, I, and I; and Fig. 4, C and C’). These results are consistent with the idea that IFT proteins are associated with IFT protein complexes and vesicles in the region surrounding the BB–centriole complex of the photoreceptor cell (Luby-Phelps et al., 2008).

Immunoelectron microscopy further revealed that the immunofluorescence labeling of IFT20 in the basal part of the CC represents the BB of the photoreceptor CC (Fig. 6 A). Similar to the other IFT proteins investigated, the immunoelectron microscopy staining of IFT20 and -52 also appeared in clusters in the cytoplasm at the periphery of the BB and the adjacent centriole of the CC (Fig. 6 A). In contrast to the group of IFT57, -88, and -140, IFT20 and -52 were absent from the ciliary groove (Figs. 5 and 6 A). However, substantial immunoelectron microscopic labeling of IFT20 and -52 was found in the cytoplasm of the periciliary collar-like extension of the photoreceptor IS (Fig. 5, A and C; and Fig. 6, A and C). In this periciliary specialization,
Figure 4. **Immunoelectron microscopic localization of IFT140 in parts of mouse photoreceptor cells.** (A and D) Electron micrographs of anti-IFT140 immunolabeling in longitudinal sections through photoreceptor ciliary apparatus. (B) Cross section through the apical CC. Anti-IFT140 labeling is detected mainly in the OS base (number signs) and at the BB. IFT140 is additionally present in the axoneme (arrowheads) projecting into the OS and in the IS below the ciliary groove (arrow) but not at the periciliary apical IS extension (asterisk). (C) In the periphery of the BB, IFT140 is associated with vesicle-like structures, highlighted by orange circles in C'. Bars: (A and C–D) 0.2 µm; (B) 0.1 µm.

Figure 5. **Immunoelectron microscopic localization of IFT52 in mouse photoreceptor cells.** (A–E) Electron micrographs of anti-IFT52 immunolabeling in sections through parts of mouse photoreceptor cells. (A) Longitudinal sections through the ciliary region (images from three different photoreceptor cells). (B) Cross section through the shaft of the CC. IFT52 immunolabeling is present at the OS base (number sign), in a particle-like structure in the shaft of the CC, and in the periciliary apical IS extension (asterisks). (C) Longitudinal section through periciliary apical IS extension (asterisks). IFT52 is labeled at vesicle-like structures, highlighted by orange circles in C'. (D) IFT52 labeling in a longitudinal section through the BB region. IFT52 is decorated at a vesicle-like structure in the periphery of the BB, highlighted by orange circles in D'. (E) Higher magnification IFT52 labeling clustered at a vesicle-like structure in the IS, highlighted by the orange circle in E'. Bars: (A) 0.4 µm; (B) 0.25 µm; (C–E') 0.1 µm.
IFT20 and -52 were concentrated in clusters at vesicle-like structures in the cytoplasm and affiliated with the membrane of the IS facing the membrane of the CC (Fig. 5, A and C; and Fig. 6, B and C). The latter periciliary membrane domain of the apical IS has been recently identified as a target for docking and fusion of cargo vesicles transported through the IS on their destination to the OS (Liu et al., 2007; Maerker et al., 2008), suggesting the involvement of IFT20 and -52 in these processes.

**Association of IFT proteins with the Golgi apparatus (GA) and post-Golgi transport vesicles**

Inspired by our aforementioned results, we next explored the subcellular distribution of IFT proteins in the Golgi regions of retinal neurons. We performed double labeling with antibodies against IFT20 and the Golgi resident GM130 (Nakamura et al., 1995), which was previously introduced as a reliable Golgi marker in photoreceptor cells (Mazelova et al., 2009). These analyses revealed a partial colocalization of IFT20 with GM130 in the IS of photoreceptor cells (Fig. 7, A and A’). In addition, we found a colocalization of IFT20 with GM130 in ganglion cells and in the nonneuronal cells of the RPE (Fig. S2 A). Immunoelectron microscopy analysis of photoreceptor cells confirmed that IFT20 is associated with the membrane stacks of the GA and vesicle-like structures, which most probably represent post-Golgi transport vesicles (Fig. 7, B–D’; Sung and Tai, 2000; Maerker et al., 2008).

Additionally, immunoelectron microscopy analysis confirmed IFT20 labeling of the GA in secondary retinal neurons (Fig. 7, F–G’). In contrast to IFT20, IFT52, -57, -88, and -140 were not detected in the Golgi of retinal cells.

**Localization of IFT proteins in dendritic processes of nonciliated retinal neurons**

The present immunofluorescence results as well as a previous study in mammalian retinas have indicated expression of IFT proteins in the OPL of the retina (Pazour et al., 2002), which contains the synapses between the photoreceptor cells and dendritic processes of secondary retinal neurons. Our present immunofluorescence data confirm the presence of IFT20, -52, and -57 but not of IFT88 and -140 in the OPL (Fig. 1 and Fig. S2 B). The precise localization of IFT proteins in the synaptic region was assessed by another series of double labeling experiments in which antibodies to the IFT proteins were colabeled with synaptic markers. Costaining of IFT proteins with antibodies against RIBEYE, a specific marker of the photoreceptor ribbon synapse (tom Dieck et al., 2005), did not show any overlap in the resulting immunofluorescence (Fig. 8, A–C). IFT20, -52, and -57 were localized below the ribbon synapse labeling of RIBEYE, indicating the presence of these IFT proteins in the postsynaptic terminals and dendritic processes of bipolar and horizontal cells. Preembedding immunoelectron microscopy analysis further confirmed postsynaptic localization of IFT proteins (Fig. 8, E–G). IFT20, -52, and -57 were concentrated in the dendritic terminals of bipolar and horizontal cells.
Figure 7. Subcellular localization of IFT20 at the GA in neurons of the mouse retina. (A–D) Localization of IFT20 in the GA of photoreceptor cells. (A) Indirect immunofluorescence of a double labeling with anti-IFT20 and anti-GM130, a marker for the GA. (A’) Higher magnification image of the indicated part (white rectangle) in A. Merged images reveal partial colocalization of IFT20 and GM130 in the GA of the IS summarized in the cartoon on the right. Asterisks indicate the apical part of the ONL. (B) Electron micrographs of anti-IFT20 immunolabeling in a cross section through the GA in the IS of a mouse photoreceptor cell. IFT20 is associated with the membrane stacks of the GA. (C and D) Anti-IFT20 labels vesicle-like structures, probably representing post-Golgi vesicles, highlighted by orange circles in C’ and D’. D and D’ are higher magnifications of B (orange rectangle). (E–G) Localization of IFT20 in the GA of secondary retinal neurons (2nd). (E) Indirect immunofluorescence of double labeling with anti-IFT20 and anti-GM130 in the OPL and
cells (Fig. 8, E–G). In addition to these IFT proteins, KIF17 was located in these postsynapses (Fig. 8 H). In no case were the presynaptic terminals of rod and cone photoreceptors stained by antibodies against IFT proteins. Furthermore, IFT20, -52, and -57 were also detected in the cytoplasm of dendritic processes of the retinal secondary neurons (Fig. 9, B–D) where the IFT proteins were clustered at vesicle-like structures (Fig. 9, B′–D′).

Discussion

In this study, we investigated the subcellular spatial distribution of five IFT particle proteins of complex A and B in cells of the mammalian retina. The applied preembedding labeling method for immunoelectron microscopy enabled spatial mapping of IFT proteins to subcellular compartments of cells and subsidiary compartments of a primary cilium for the first time. In addition, it allowed the identification of ciliary cargo vesicles associated with the IFT proteins (Sedmak et al., 2009). Our results confirm the central function of IFT molecules in cilary transport and further strengthen their role in transport processes in the cytoplasm of ciliated cells but also of nonciliated cells.

IFT proteins participate in all modules of the molecular transport destined to photoreceptor cilia

We provide evidence that IFT particle proteins participate in all principle modules of the transport destined to the photoreceptor cilium necessary for ciliogenesis (photoreceptor OS formation) and the maintenance of the light-receptive OS (Fig. 10 A). Localization of IFT20 in the GA and its association with transport vesicles in the cytoplasm of all retinal cell types and of the adjacent RPE support the model of the general nonciliary function of IFT20 as a molecular mediator between the sorting machinery of the GA, the vesicular transport of cilia components, and their delivery to the cilary base (Follit et al., 2006, 2008). In the GA, IFT20 is thought to be anchored to Golgi membranes by the golgin protein GMAP210, and after vesicle budding, IFT20 marks the ciliary-destined vesicles that translocate from the Golgi to the base of the cilium, where IFT20 binds to other complex B subunits (Follit et al., 2006, 2008; Omori et al., 2008).

In photoreceptor cells, we monitored IFT20-associated vesicles on their track through the IS to the base of the CC. In the defined periciliary compartment, all five IFT proteins studied were abundantly concentrated and associated with cargo vesicles. These findings affirm previous results (Pazour et al., 2002; Luby-Phelps et al., 2008) and thereby support the hypothesis of the assembly and arrangement of IFT complexes at the base of cilia and flagella (Rosenbaum and Witman, 2002; Pedersen and Rosenbaum, 2008). As in other ciliary systems, all IFT molecules were found to be associated with Golgi-derived transport vesicles in photoreceptor cells. Previous experiments showed that the visual pigment rhodopsin is transported along microtubules by cytoplasmic dynein to the periciliary apical membrane of the IS (Fig. 10 A; Tai et al., 1999). At the ciliary base of photoreceptors, the cargo is transferred from the module of the cytoplasmic IS transport to the module of ciliary delivery, in particular to the ciliary IFT system (Papernow, 2002; Roepman and Wolfrum, 2007). This transfer of membrane cargo to the specialized periciliary membrane domain is in principle an exocytotic process. The certain involvement of IFT molecules in this process supports the hypothesis that the evolution of eukaryotic cilia and in particular the IFT system is originated from the exocytotic system in ancestral nonciliated cells (Avior-Reiss et al., 2004; Jékely and Arendt, 2006). Nevertheless, present immunoelectron microscopy data revealed slightly different localizations of IFT proteins in this periciliary region (Fig. 10 A): IFT57, -88, and -140 were found beneath the groove formed by the transition of the ciliary membrane and the plasma membrane. In contrast, IFT20 and -52 were located in the apical extension of the IS. The latter region we recently identified as a periciliary target membrane for ciliary-destined transport vesicles in mammalian photoreceptor cells (Maerker et al., 2008). The differential distribution of IFT protein subsets may depend on the sequential assembly of IFT particles for the delivery into the cilium. However, because there is no overlap between the membrane localization of the two IFT protein subsets, they may be associated with different ciliary cargoes, which are independently delivered to different target zones in the periciliary compartment. In photoreceptor cells, different transport routes through the IS were recently suggested for different OS cargos (Karan et al., 2008; Bhownick et al., 2009), making different target zones in the IS plausible.

In addition to their abundant concentration at the cilium base, IFT proteins were found in the distinct parts of the primary cilium of photoreceptors: in the BB, the CC, the basal OS, and the axoneme (Fig. 1). In the region of the BB, all IFT proteins were present and associated with cargo vesicles. In the CC, IFT52, -57, -88, and -140 were detected alongside the microtubule doublets, but IFT20 was absent. This confirms previous studies and supports the hypothesis that the first set of IFT proteins participates in the molecular cargo trafficking or is transported as cargo (in the case of complex A component IFT140, which is thought to be involved in retrograde IFT) through the CC (Rosenbaum et al., 1999; Baker et al., 2004; Insinna and Besharse, 2008; Insinna et al., 2008, 2009; Krock and Perkins, 2008; Luby-Phelps et al., 2008; Pedersen and Rosenbaum, 2008; Pigino et al., 2009). The faint decoration of the IFT proteins in the shaft of the CC by immunofluorescence and immunoelectron microscopy may reflect the velocity of the IFT particles as they pass through the CC. The concentration of IFT57, -88, and -140 at the base of the OS indicates a certain role of these IFT proteins in the formation of novel photosensitive...

processes associated with the transport of cargo that is not incorporated into the nascent disks at the OS base and translocates along the microtubules of the axoneme in the OS. All three IFT proteins are decorated in dendritic processes of second neurons. (B–D) High magnification details of B–D indicating the association of IFT20, -52, and -57 with vesicle-like structures highlighted by orange circles. Arrows indicate the synaptic ribbon, and triangles and asterisks highlight bipolar and horizontal cells, respectively. Bars: (B–D) 0.2 µm; (B′–D′) 0.1 µm.

Figure 9. Localization of IFT20, -52, and -57 in dendritic processes of secondary retinal neurons. (A) Cartoon of the organization of an OPL synapse connection between a rod photoreceptor cell (PR) and the secondary retinal neurons (2nd), bipolar cells (triangle), and horizontal cells (asterisks). D, dendritic processes. (B–D) Electron micrographs of immunolabeling of IFT20, -52, and -57 in the OPL of mouse retinas. All three IFT proteins are decorated in dendritic processes of second neurons. (B′–D′) High magnification details of B–D indicating the association of IFT20, -52, and -57 with vesicle-like structures highlighted by orange circles. Arrows indicate the synaptic ribbon, and triangles and asterisks highlight bipolar and horizontal cells, respectively. Bars: (B–D) 0.2 µm; (B′–D′) 0.1 µm.
in the OS independently from the disk neogenesis, are, for example, arrestin and the visual G-protein transducin, which light-dependently cycle between the inner and the OS (Calvert et al., 2006). Recent data indicate that these bidirectional movements are dependent on the axonemal microtubule track (Peterson et al., 2005; Reidel et al., 2008; Orisme et al., 2010). The IFT complex B protein IFT88 may contribute to the translocation of both signaling molecules into the OS during photoreceptor adaptation, whereas, in the clearance of transducin and arrestin from the OS, the IFT complex A compound IFT140 may participate. Our findings confirm previous observations in other cilia and flagella, in which sets of IFT components were also found to be sequentially organized or spatially distributed in ciliary subcompartments (Evans et al., 2006; Ou et al., 2007; Lee et al., 2008).

**IFT20 is not a component of the IFT core complex B in photoreceptor cilia**

In contrast to all other IFT molecules investigated, we did not find IFT20 in the CC of photoreceptor cells. The present subcellular mapping by the sophisticated light and electron microscopy consistently revealed that IFT20 is restricted to the periciliary cytoplasm of the apical IS and the BB but is neither present in the CC nor in more apical sections of the photoreceptor cilium in all species investigated. This is in contrast to previous studies suggesting a ciliary localization of IFT20 (Pazour et al., 2002; Follit et al., 2006, 2008, 2009). Follit et al. (2006) discuss that the ciliary detection is dependent on the fixation protocol because of epitope masking after fixation, which our control experiments did not confirm. Nevertheless, all published immunofluorescence data on the intrinsic IFT20 ciliary staining are not convincing, and a solid ciliary localization of IFT20 is only found after IFT20 overexpression (Follit et al., 2006, 2008). It is possible that the high sensitivity of the elaborated techniques used in this study is still not sensitive enough for the detection of IFT20 in photoreceptor cilia or that IFT20 epitopes are not accessible for the antibodies because of variations in the composition and position of the IFT molecules in the particles. Nevertheless, we believe that IFT20 is not present in photoreceptor cilia. IFT20’s absence from the ciliary IFT complex B is supported by the lack of IFT20 in IFT particle fractions of gradients derived from photoreceptors (Baker et al., 2003) and unpublished data on proteomic dissection of the complex B in cultured mammalian cells. Furthermore, the analysis of complex B composition in Chlamydomonas demonstrated that IFT20 is linked to a complex B core by weak and
Evidence for a novel IFT system in dendrites of nonciliated retinal neurons

Besides the presence of IFT20 in the GA, IFT systems were recently found in nonciliated cells, associated with exocytosis at the immune synapse required for T cell interaction with antigen-presenting cells (Finetti et al., 2009; Baldari and Rosenaum, 2010). In the mammalian retina, a weak immunoreactivity for IFT proteins present in the OPL was construed as a localization of IFT proteins in the photoreceptor synaptic terminals (Pazour et al., 2002). The latter finding, together with IFT-associated kinesin-II localization at these synapses (Muresan et al., 1999), raised the possibility of a function of IFT proteins in presynaptic terminals (Pazour et al., 2002). Nevertheless, in this study, we show that IFT20, -52, and -57 proteins are localized not in the presynaptic terminals of photoreceptor cells but in the postsynaptic terminals of the bipolar and horizontal cells. Double immunofluorescence staining with synaptic markers and preembedding labeling of IFT molecules conclusively revealed localization of the three IFT molecules in the postsynaptic dendritic terminals and dendritic shafts of secondary retinal neurons. This spatial distribution and the association of these IFT molecules with cytoplasmic membrane vesicles suggest participation of an IFT system at the vesicular transport to the specialized membrane of the postsynaptic dendritic terminal (Fig. 10 B). It has been demonstrated that the kinesin-II family member KIF17 navigates large protein complexes containing subunits of neurotransmitter receptors to the postsynaptic membrane (Setou et al., 2000; Guillaud et al., 2003). In secondary retinal neurons, KIF17 regulates the dendritic transport of glutamate receptor subunits to the postsynaptic membrane (Qin and Pourcho, 2001; Kayadjanian, et al., 2007). It is notable that the specific targeting of neurotransmitter receptors is critically important for plasticity of the postsynaptic terminal and might be a regulatory point for synaptic plasticity and neuronal morphogenesis. KIF17 has been found as an alternative kinesin motor to kinesin-II in IFT (Signor et al., 1999b). In the vertebrate retina, KIF17 was identified as part of a protein complex containing IFT20 and -57, which is essential for photoreceptor OS development (Insinna et al., 2008, 2009). Our present data indicate that the dendritic processes of secondary retinal neurons contain a nonciliary IFT protein complex that includes IFT20, -52, and -57 and KIF17 but neither IFT88 nor the heterotrimeric kinesin-II (Fig. 10 B). Thus, the nonciliary dendritic IFT complex differs in its composition from the one recently described for the immune synapse (Finetti et al., 2009). We reason that IFT protein complexes are modularly composed and that their defined arrangement may be cell specific and/or dependent on a particular role of the IFT protein complex in intracellular membrane trafficking to selective target membranes.

**Materials and methods**

**Animals, tissue dissection, and human tissue**
All experiments conformed to the statement by the Association for Research in Vision and Ophthalmology regarding the care and use of animals in research. Mature C57BL/6J mice were maintained on a 12-h light–dark cycle, with food and water ad libitum. After the sacrifice of animals, eyeballs were dissected for further analyses. Bovine eyes were obtained from the local slaughter house. Human eyes (female, age 78, 13 h postmortem) were donated (Department of Ophthalmology, University Medical Center of the Johannes Gutenberg University Mainz). Informed consent was obtained for subjects; procedures adhered to the Declaration of Helsinki and were approved by the local review board. Retina was isolated from eyeball and further processed for immunofluorescence analysis as described in Immunofluorescence microscopy.

**Antibodies and fluorescent dyes**
Antisera against IFT20, -52, -57, -88, and -140 proteins were raised in rabbit, and affinity-purified antibodies used in this study were previously characterized (Pazour et al., 2002; Baker et al., 2003; Folliet et al., 2006) and provided by G.J. Pazour (University of Massachusetts Medical School, Worcester, MA). Monoclonal antibodies to centrin-3 were used as a molecular marker for the ciliary apparatus of photoreceptors (Trojan et al., 2008). Monoclonal mouse antibodies to RIBEYE (CIBP2) and to the Golgi-resident GM130 were purchased from BD and were previously used as a cis and medial Golgi marker in photoreceptor cells by Mazelova et al. (2009). Polyclonal rabbit anti-KIF17 was obtained from Abcam and previously used in Insinna et al. (2009). Anti-RP1 antibody raised in chicken was a gift from E.A. Pierce (University of Pennsylvania School of Medicine, Philadelphia, PA; Liu et al., 2002). Secondary antibodies Alexa Fluor 488 or 568 (Invitrogen), IRDye 680 or 800 (Rockland), donkey anti-rabbit horse conjugated with reddish peroxidase (GE Healthcare), and biotinylated secondary antibodies (Vector Laboratories) were used. Nuclear DNA was stained by 1 µg/µl DAPI (Sigma-Aldrich).

**Western blot analyses**
For Western blot analyses, isolated mouse retinas and testes were homogenized in buffer containing a protease inhibitor cocktail (Roche). Samples were extracted in modified radioimmunoprecipitation assay buffer (50 mM Tris-HCl, 150 mM NaCl, 0.1% SDS, 2 mM EDTA, 1% NP-40, 0.5% Na deoxycholate, 1 mM Na vanadate, and 30 mM Na-pyrophosphate, pH 7.4). For denaturing gel electrophoresis, samples were mixed with SDS-PAGE sample buffer (62.5 mM Tris-HCl, 10% glycerol, 2% SDS, 5% mercaptoethanol, 1 mM EDTA, and 0.025 mM bromophenol blue, pH 6.8). Protein extracts from retinas and testes were separated on 12% or 15% polyacrylamide gels, respectively, and transferred onto polyvinylidene difluoride membranes (Millipore). The membrane was blocked with blocking reagent (AppliChem) or nonfat dry milk (AppliChem) for 2 h at room temperature. Immunoreactivity was detected by the appropriate primary and corresponding secondary antibodies using an infrared imaging system (Odyssey; LI-COR Biosciences) for AppliChem-blocked membrane or the chemiluminescence detection system (ECL Plus Western blotting detection system; GE Healthcare) for nonfat dry milk–blocked membrane. In the latter case, ECL-exposed and developed xray films were scanned using a Duoscan T2500 (Agfa-Gevaert), and images were processed in Photoshop CS (Adobe Systems).
Immunofluorescence microscopy
Eyes of adult mice were placed in tissue-freezing medium [Leica] enclosed by boiled-liver block and cryofixed in melting isopentane (Wolffram, 1991). Mouse eyes were sectioned in 10-μm cryosections at −20°C in a cryostat (HM 560 Cryo-Star; MICROM). Cryosections were placed on poly-l-lysine precoated coverslips. Some cryosections were additionally fixed for 1 min in cold methanol containing 0.5% EGTA and washed with PBS. After incubation with 0.01% Tween 20 in PBS, PBS-washed sections were incubated with blocking solution (0.5% cold-water fish gelatin and 0.1% ovalbumin in PBS), followed by overnight incubation with primary antibodies, and diluted in blocking solution at 4°C. Washed cryosections were incubated with Alexa Fluor-conjugated secondary antibodies in PBS with DAPI. After PBS washes, sections were mounted in Moviol 4:88 (Roche) and visualized in a microscope (Leica DM/MBB; Leica) through a 63× 1.32 HCl Plan-Apochromat and a 100× NA 1.3 Plan-Fluotar oil objective lens. Images were obtained with a charge-coupled device camera (ORCA ER; Hamamatsu Photonics). Image acquisition was always performed at the same gain and exposure settings. Image contrast was adjusted offline with Photoshop CS using different tools, including color correction and pixel resampling.

Immunoelectron microscopy
For immunoelectron microscopy, a recently introduced protocol was applied (Maerker et al., 2008; Sedmak et al., 2009). During fixation of isolated mouse eyes in 4% PFA in Sorenson buffer (0.1 M Na2HPO4·2H2O and 0.1 M KH2PO4, pH 7.4), eyes were perforated, and lenses were removed. Washed retinas were dissected from eye cups and infiltrated with 10 and 20% sucrose in Sorenson buffer, followed by incubation in buffered 30% sucrose overnight. After four cycles of freezing in liquid nitrogen and thawing at 37°C, retinas were washed in PBS and embedded in buffered 2% Agar (Sigma-Aldrich). Agar blocks were sectioned with a Vibratome (VT 1000 S; Leica) in 50-μm slices. Vibratome sections were blocked in 10% normal goat serum and 1% bovine serum albumin in PBS and subsequently incubated with primary antibodies against IFT protein(s) for 4 days at 4°C. After washing with PBS, the appropriate biotinylated secondary antibodies were applied to the sections. After PBS washes, antibody reactions were visualized by a Vectastain ABC kit (Vector Laboratories) according to the manufacturer’s instructions. The Vectastain ABC kit provides the avidin-biotin HRP complex (ABC), which binds the biotin-conjugated secondary antibodies. The immunocomplex was visualized with an avidin-biotin HRP complex (ABC), which binds the biotin-conjugated secondary antibodies. The immunocomplex was visualized with a charge-coupled device camera (ORCA ER; Hamamatsu Photonics). Image acquisition was always performed at the same gain and exposure settings. Image contrast was adjusted offline with Photoshop CS using different tools, including color correction and pixel resampling.
