*D. melanogaster* macrophages are highly migratory cells that lend themselves beautifully to high resolution in vivo imaging experiments. By expressing fluorescent probes to reveal actin and microtubules, we can observe the dynamic interplay of these two cytoskeletal networks as macrophages migrate and interact with one another within a living organism. We show that before an episode of persistent motility, whether responding to developmental guidance or wound cues, macrophages assemble a polarized array of microtubules that bundle into a compass-like arm that appears to anticipate the direction of migration. Whenever cells collide with one another, their microtubule arms transiently align just before cell–cell repulsion, and we show that forcing depolymerization of microtubules by expression of Spastin leads to their defective polarity and failure to contact inhibit from one another. The same is true in orbit/clasp mutants, indicating a pivotal role for this microtubule-binding protein in the assembly and/or functioning of the microtubule arm during polarized migration and contact repulsion.

**Introduction**

It is well established that the microtubule cytoskeleton in numerous cell types plays a role in generating and maintaining polarity (Siegrist and Doe, 2007). During cell migration for example, the directed polymerization of microtubules into the leading edge is required to either establish and/or maintain the front and back organization necessary for directed movement (Small et al., 2002); this central polarity determinant must also be able to rapidly reorganize whenever a cell repolarizes in response to guidance cues. Many extracellular cues that guide a cell’s movement are soluble factors, but another important cue, particularly in vivo as cells move through tissues, will be collisions with other cells. Contact repulsion was first described more than 50 yr ago when fibroblasts were observed in vitro to rapidly repolarize upon cell–cell contact (Abercrombie and Heaysman, 1953, 1954). Since this initial observation, we have gleaned little molecular understanding of how cell–cell repulsion is regulated and only recently have begun to observe this phenomenon during migratory events in vivo (Carmona-Fontaine et al., 2008). In this study, we show that *Drosophila melanogaster* macrophages undergo contact repulsion during developmental dispersal in vivo and that this process is important in maintaining an even distribution of these cells within the animal. Using fluorescent probes specific to actin and microtubules, we observe the interplay of these cytoskeletal networks within hemocytes and reveal that the rapid cellular repolarization observed upon cell collisions is preceded by alignment of stable arm-like microtubule bundles in the colliding cells. We demonstrate that these microtubule arms are critical for contact repulsion and that their formation is regulated by the plus end microtubule–interacting protein Orbit.
in these cells. To visualize microtubule dynamics, we generated a fusion protein consisting of the microtubule-binding domain of human CLIP170 (Diamantopoulos et al., 1999; Perez et al., 1999) fused to mCherry or GFP. Coexpression of mCherry-CLIP170 and a fluorescent filamentous actin–binding construct (GFP-Moesin; Dutta et al., 2002) specifically within hemocytes allowed colabeling of both actin and microtubules in individual hemocytes within living embryos. Confocal imaging of these cells in situ as they underwent their developmental migrations or in vitro when plated out on a coverslip revealed that microtubules arranged themselves into a basket surrounding the cell body, with some extending into the lamellae (Fig. 1 a and Fig. S1 d). The lamellar microtubules of hemocytes in vivo are highly dynamic and display similar cycles of growth, pausing, catastrophe, and regrowth (Fig. 1, b and d). Expression of two copies of the fluorescent CLIP170 construct in hemocytes in vivo revealed the entire length of microtubules (Fig. 1, a and d), whereas reduced expression (only a single copy) highlighted the plus end of

**Results and discussion**

**Colabeling of microtubules and actin in Drosophila macrophages reveals the dynamic interplay of these two cytoskeletal networks**

During development, *Drosophila* embryonic macrophages (hemocytes) disperse from their origin in the head and migrate throughout the embryo, such that by the end of embryogenesis, they are evenly distributed within the organism (Wood and Jacinto, 2007). Much of this dispersal occurs within a space between the superficial epithelium and subjacent tissues (ventrally, the ventral nerve cord), which is otherwise devoid of other cell types (Fig. S1, a–c), obliging hemocytes to interact only with one another. The organization and dynamics of the actin cytoskeleton in embryonic hemocytes has been well studied during their developmental migrations and their response to tissue damage (Stramer et al., 2005; Wood et al., 2006). In contrast, nothing is known about how microtubules are distributed in these cells. To visualize microtubule dynamics, we generated a fusion protein consisting of the microtubule-binding domain of human CLIP170 (Diamantopoulos et al., 1999; Perez et al., 1999) fused to mCherry or GFP. Coexpression of mCherry-CLIP170 and a fluorescent filamentous actin–binding construct (GFP-Moesin; Dutta et al., 2002) specifically within hemocytes allowed colabeling of both actin and microtubules in individual hemocytes within living embryos. Confocal imaging of these cells in situ as they underwent their developmental migrations or in vitro when plated out on a coverslip revealed that microtubules arranged themselves into a basket surrounding the cell body, with some extending into the lamellae (Fig. 1 a and Fig. S1 d). The lamellar microtubules of hemocytes in vivo are highly dynamic and display similar cycles of growth, pausing, catastrophe, and regrowth (Fig. 1, b and d). Expression of two copies of the fluorescent CLIP170 construct in hemocytes in vivo revealed the entire length of microtubules (Fig. 1, a and d), whereas reduced expression (only a single copy) highlighted the plus end of
Contact inhibition in Drosophila macrophages • Stramer et al.

Macrophage microtubules are bundled into a microtubule arm during in vivo directed motility

Live imaging of hemocytes as they migrate within the embryo showed that as microtubules extend into the lamellae, they are driven back apparently by actin retrograde flow and consequently converge on one another to form a stable population of centrally located microtubule bundles that coalesce to form what we termed a microtubule arm (Fig. 2 a and Video 2). This structure was not an artifact of CLIP170 overexpression and is absolutely dependent on a cell being polarized because we never observed arms in hemocytes plated out from the embryo onto a coverslip, where they failed to exhibit a polarized morphology (Fig. S1 d). We repeated the experiments using Tau-GFP, a construct widely used to label microtubules in Drosophila (Brand, 1995), and found similar microtubule dynamics in hemocytes as they migrated within the embryo (Fig. S1 e). Within a stage 15 embryo, the majority of hemocytes (81%; n = 37) displayed a clearly defined microtubule arm, which appeared to assign the cell front such that migration was always in the direction of the microtubule bundle. To assess whether assembly of this structure affects the migratory capacity of the cell, we measured directional persistence in migrating hemocytes with and without a well-defined microtubule arm and found that hemocytes with an arm have a directional persistence of 89.2 ± 1.5% (mean ± SEM; n = 18) as opposed to 18.5 ± 1.6% (n = 18) for those that lack this structure. We also noted that upon turning in response to developmental guidance cues, a hemocyte will maintain and reorient the same microtubule arm if the turn angle is <40° (92.3% of cells analyzed; n = 26); however, if the angle is >40°, the cell generally dismantles its microtubule bundle and forms a new one in the future direction of travel (88.8% of cells analyzed; n = 27). To determine whether extension of a microtubule arm directs lamellar polarization or is simply its consequence, we examined lamellar and microtubule dynamics within hemocytes responding to a polarizing chemotactic cue. We made laser wounds to embryos, which rapidly induced hemocyte migration toward the site of damage (Stramer et al., 2005, 2008), and imaged the microtubule architecture in responding cells.

Macrophage microtubules are bundled into a microtubule arm during in vivo directed motility.

Live imaging of hemocytes as they migrate within the embryo showed that as microtubules extend into the lamellae, they are driven back apparently by actin retrograde flow and consequently converge on one another to form a stable population of centrally located microtubule bundles that coalesce to form what we termed a microtubule arm (Fig. 2 a and Video 2). This structure was not an artifact of CLIP170 overexpression and is absolutely dependent on a cell being polarized because we never observed arms in hemocytes plated out from the embryo onto a coverslip, where they failed to exhibit a polarized morphology (Fig. S1 d). We repeated the experiments using Tau-GFP, a construct widely used to label microtubules in Drosophila (Brand, 1995), and found similar microtubule dynamics in hemocytes as they migrated within the embryo (Fig. S1 e). Within a stage 15 embryo, the majority of hemocytes (81%; n = 37) displayed a clearly defined microtubule arm, which appeared to assign the cell front such that migration was always in the direction of the microtubule bundle. To assess whether assembly of this structure affects the migratory capacity of the cell, we measured directional persistence in migrating hemocytes with and without a well-defined microtubule arm and found that hemocytes with an arm have a directional persistence of 89.2 ± 1.5% (mean ± SEM; n = 18) as opposed to 18.5 ± 1.6% (n = 18) for those that lack this structure. We also noted that upon turning in response to developmental guidance cues, a hemocyte will maintain and reorient the same microtubule arm if the turn angle is <40° (92.3% of cells analyzed; n = 26); however, if the angle is >40°, the cell generally dismantles its microtubule bundle and forms a new one in the future direction of travel (88.8% of cells analyzed; n = 27). To determine whether extension of a microtubule arm directs lamellar polarization or is simply its consequence, we examined lamellar and microtubule dynamics within hemocytes responding to a polarizing chemotactic cue. We made laser wounds to embryos, which rapidly induced hemocyte migration toward the site of damage (Stramer et al., 2005, 2008), and imaged the microtubule architecture in responding cells.

Figure 2. Microtubules are transiently bundled within the lamellae of migrating hemocytes. (a) Live imaging of a hemocyte expressing GFP-Moesin (actin) and mCherry-CLIP170 (microtubules) revealed dynamic microtubules rapidly bundling into an arm (arrow) to polarize the cell’s morphology. (b) After laser ablation, a hemocyte (asterisks) in the vicinity of the wound extends a microtubule arm (arrows) before acquisition of a polarized lamellar morphology. The dashed lines indicate the wound edge. Time is shown in seconds. Bars, 10 µm.
we live-imaged cytoskeletal dynamics during hemocyte contact inhibition. Confocal imaging showed that when two hemocytes came into contact, their microtubule arms rapidly aligned (Fig. 3, b and c; and Video 5). Higher magnification time-lapse videos revealed that there was initial contact between lamellae and alignment of actin filaments, followed by a transient alignment of microtubule arms (Fig. 3 c and Video 6). This interaction lasted for \( \approx 3 \) min before arms collapsed, and the cells subsequently re-polarized and migrated away from one another (Fig. 3 c and Video 6).

We then examined the turn angles 3 min after microtubule arms contacted and compared this with the turn angles of hemocytes that did not collide. Freely moving cells tended to maintain their course of direction, whereas cells that had collided showed a much greater change in direction after cell collision (\( P < 0.01; \chi^2 \) test). The microtubule cytoskeleton is also required for cell–cell repulsion.

Analysis of stage 15 embryos showed that upon contact with one another, hemocytes rapidly stopped migrating and re-polarized before moving away from each other (Fig. 3 a and Video 4) in a process reminiscent of the contact inhibition first observed in cultured fibroblasts more than 50 yr ago (Abercrombie and Heaysman, 1953). To understand how this repolarization occurs, we live-imaged cytoskeletal dynamics during hemocyte contact inhibition. Confocal imaging showed that when two hemocytes came into contact, their microtubule arms rapidly aligned (Fig. 3, b and c; and Video 5). Higher magnification time-lapse videos revealed that there was initial contact between lamellae and alignment of actin filaments, followed by a transient alignment of microtubule arms (Fig. 3 c and Video 6). This interaction lasted for \( \approx 3 \) min before arms collapsed, and the cells subsequently re-polarized and migrated away from one another (Fig. 3 c and Video 6).
Coexpression of GFP-CLIP170 within these hemocytes revealed that Spastin prevents assembly of a normal microtubule cytoskeleton (Fig. 4, a vs. b). Early developmental dispersal of hemocytes along the ventral midline in these embryos was delayed (Fig. S2, g and h); nonetheless, most hemocytes found their way to the ventral midline by stage 14, unlike hemocytes in mutants such as Rac that show a more catastrophic defect in migration and generally fail even to leave the head (Paladi and Tepass, 2004; Stramer et al., 2005). Interestingly, despite not being able to form a microtubule arm, these cells were still able to respond to wound stimuli, although with less efficiency than wild type; tracking experiments revealed individual cells taking a more tortuous route to the wound and displaying a mean directional persistence of 47.4 ± 3.8% (mean ± SEM) as opposed to 70.4 ± 3.7% for wild-type cells (Fig. S2, b and c). Interestingly, this failure to maintain directional persistence is countered by an increase in speed with mutant cells migrating at a mean of 4.02 ± 0.3 µm/min (mean ± SEM) when compared with wild types (2.36 ± 0.2 µm/min) such that the number of Spastin-expressing cells present at a wound 1 h after ablation is only slightly reduced relative to wild-type controls (Fig. S2 a). A more dramatic migration phenotype was seen from stage 15 onwards when Spastin-expressing hemocytes failed to disperse from the ventral midline (Fig. 4, d vs. e). Live imaging revealed that these hemocytes were unable to polarize and remained in close contact with one another at stages when they would ordinarily be exhibiting contact repulsion from one another (Video 7). To quantify these hemocyte dispersal defects, we performed a nearest neighbor analysis whereby the mean distance between each hemocyte and its nearest neighbor ($d_n$) was measured. Spastin-expressing cells showed a significant reduction in $d_n$ when compared with wild type (11.68 µm vs. 15.69 µm, respectively; $P < 0.001$; Fig. S3, a, b, and e). To further quantify this deficiency in contact repulsion, we measured the length of time that wild-type versus Spastin-expressing hemocytes remained in contact with one another. We found that although wild-type hemocytes were rarely in contact with their neighbors for >10 min, Spastin-expressing hemocytes frequently retained contacts for >15 min (Fig. 4 j). Collectively, these results demonstrate that microtubules and, specifically, the microtubule arm we observe in hemocytes in vivo are essential to maintain a polarized morphology in hemocytes and, furthermore, are necessary for efficient cell–cell repulsion.

Disruption of the microtubule-stabilizing protein Orbit leads to a disorganized microtubule cytoskeleton and contact repulsion defects

A previous study implicated the microtubule plus end–binding and –stabilizing protein Orbit/Clasp in mediating growth cone repulsion from the chemorepellent Slit in Drosophila embryos (Lee et al., 2004). Given the similarity between the microtubule architecture in hemocytes and that seen in neuronal growth cones, we wondered whether Orbit might also mediate cell–cell repulsion in hemocytes. To address this, we analyzed hemocyte migration in orbit2 mutant embryos. Similar to those expressing Spastin, orbit2 mutant hemocytes exhibited a delay in migration along the ventral midline (Fig. S2, i and j), as well as a more severe defect whereby individual hemocytes failed to distribute themselves evenly at stage 15 (Fig. 4, d vs. f). Consistent with a defect in contact repulsion, quantitative analysis showed that orbit2 cells had a reduction in $d_n$ indistinguishable from Spastin-expressing cells (11.70 µm vs. 11.68 µm, respectively; $P > 0.1$; Fig. S3, b, c, and e). Furthermore, similar to Spastin-expressing
cells, orbit\textsuperscript{2} hemocytes were frequently seen in contact with their neighbors for >15 min (Fig. 4 j). However, orbit\textsuperscript{1} hemocytes, like Spastin-expressing cells, were still capable of migrating to both epithelial wounds and in response to developmental guidance cues (Fig. S2, a, i, and j), demonstrating that this contact repulsion defect is not caused by a more general defect in motility. Furthermore, just as observed for Spastin-expressing cells, Orbit mutant hemocytes migrating to wounds exhibited reduced directional persistence (49.4\% ± 3.7) and an increase in migration speed (3.19 ± 0.12 μm/min) when compared with wild-type cells (Fig. S2 d). To understand how a loss of Orbit affects the microtubule cytoskeleton, we expressed a single copy of GFP-CLIP170 to reveal microtubule dynamics in orbit\textsuperscript{1} hemocytes. Microtubules in mutant cells were highly dynamic and able to both polymerize and undergo catastrophe. However, unlike in wild-type cells, microtubule polymerization was unpolarized (Fig. S3 f); no microtubules became stabilized or bundled, and we saw no sign of a microtubule arm (Fig. 4 c and Video 8). Expression of a functional GFP-Orbit fusion protein (Lee et al., 2004), specifically in orbit\textsuperscript{1} hemocytes, rescued the formation of this structure (Fig. 4, g–i), and time-lapse analysis of these cells revealed GFP-Orbit localizing to the ends of growing microtubules as well as to the microtubule arm and the basket surrounding the cell body (Fig. 4 k). In addition to rescuing the microtubule architecture, hemocyte-specific expression of Orbit was able to restore contact repulsion such that d\textsuperscript{w} and contact time between cells both returned to wild-type levels (Fig. 4 j and Fig. S3, d and e). These data demonstrate that Orbit is required for the stabilization and bundling of microtubules and that this architecture is important for both polarity and contact repulsion in hemocytes.

Our observation of microtubules in Drosophila hemocytes in vivo revealed that although these cells have some similarities with isolated cells in vitro, they also exhibit significant and interesting differences. Hemocytes in vivo, like many cultured cells (e.g. S2 cells), do possess a dynamically unstable population of microtubules in the lamellae. However, hemocytes in vivo also assemble a stable basket of microtubules surrounding the cell body and a microtubule arm that protrudes into the lamellae and polarizes the cell. Although it is possible that this architecture is unique to hemocytes, it appears more likely that the differences are a result of the 3D environment in which the hemocyte migrates in vivo because Drosophila hemocyte cell lines (Rogers et al., 2004; Sousa et al., 2007), and more revealingly primary isolated hemocytes plated onto a 2D substrate in vitro (Fig. S1 d), do not show a bundled microtubule architecture. Furthermore, none of these cells in vitro have a polarized morphology. Interestingly, it was recently reported that fibroblasts migrating in vitro on 1D lines of matrix move with an anterior microtubule bundle mimicking the movement we observe for hemocytes in vivo (Doyle et al., 2009). Hemocyte cell lines are increasingly being used as screening tools to elucidate genes controlling several processes such as cytoskeletal regulation (Kiger et al., 2003; Rogers et al., 2003), and more revealingly primary isolated hemocytes plated onto a 2D substrate in vitro (Fig. S1 d), do not show a bundled microtubule architecture. Furthermore, none of these cells in vitro have a polarized morphology. Interestingly, it was recently reported that fibroblasts migrating in vitro on 1D lines of matrix move with an anterior microtubule bundle mimicking the movement we observe for hemocytes in vivo (Doyle et al., 2009). Hemocyte cell lines are increasingly being used as screening tools to elucidate genes controlling several processes such as cytoskeletal regulation (Kiger et al., 2003; Rogers et al., 2003). However, to date, no in vitro screen has highlighted orbit or actin regulatory genes such as fascin as important for cellular morphology (Kiger et al., 2003; Rogers et al., 2003; Baum, B., personal communication), but we know that they play a role within hemocytes in vivo (Zanet et al., 2009; this study). Our findings indicate that microtubule organization is very different in hemocytes in the embryo and highlight the importance of complementing in vitro screens with in vivo analysis.

Obvious similarities exist between the cytoskeletal architecture within hemocytes in vivo and that seen in migrating neuronal growth cones: both possess a central bundle of microtubules and actin microspikes radiating from the cell body toward the cortex. In both cell types, the local modification of microtubule dynamics appears capable of regulating directed migration. However, in this study, we also show that microtubules are critical for mediating cell–cell repulsive events in hemocytes (Fig. 5). That microtubules may have a role in both directed migration and contact repulsion initially seems paradoxical but, in fact, has a simple explanation that may parallel microtubule roles in growth cone guidance. Stabilization of growth cone microtubules in the direction of a chemotactic cue leads to the cell turning toward this signal (Zhou et al., 2004; Zumbrunn et al., 2001), whereas local depolymerization of microtubules results in the opposite event, cell repulsion (Buck and Zheng, 2002). Indeed, when microtubule dynamics are altered in neurons, growth cones fail to turn in response to many different cues (Williamson et al., 1996; Lee et al., 2004; Rajnicek et al., 2006). Our data suggest that cell collision is simply another guidance cue requiring a dynamic microtubule cytoskeleton that rapidly collapses upon cell–cell contact to enable cell–cell repulsion and turning.

How might microtubules be directed to disassemble upon cell–cell contact, and how does this lead to cell repulsion? Previous studies showed that catastrophe of microtubules is induced by their growth against an immovable cellular object (Janson et al., 2003; Laan et al., 2008). The collision of two growing microtubules in colliding hemocytes may generate sufficient force for their depolymerization, which would lead to stochastic cellular repolarization. Another, nonmutually exclusive possibility is that microtubules play an active signaling role to break cell contacts. Fibroblasts undergoing contact inhibition in vitro make transient cell–cell adhesions (Glouchankova et al., 1998; Omelchenko et al., 2001), and the alignment of cytoskeletal filaments between two colliding hemocytes suggests similar transient contacts. Microtubules have also been shown to target focal adhesions in fibroblasts to induce their disassembly (Kaverina et al., 1999), leading to the intriguing possibility that cell–cell contacts might be another form of adhesion regulated by microtubules.

One final question is whether or not the repolarization event itself is actively signaled or is a passive consequence of microtubule reorganization. It was recently reported that when two neural crest cells collide, RhoA becomes transiently activated at the site of cell–cell contact (Carmona-Fontaine et al., 2008) and may therefore provide a cell repolarization signal during contact inhibition. Intriguingly, microtubules are capable of regulating Rho signaling by interactions with Rho guanine nucleotide exchange factors (Ren et al., 1998; Glaven et al., 1999; van Horck et al., 2001; Krendel et al., 2002; Rogers et al., 2004). These data are interesting in light of our previous finding that Rho mutant hemocytes clump and maintain cell–cell contacts.
Figure 5. Model for how microtubule bundles regulate both polarized migration and contact repulsion in hemocytes. (a) Stabilized, Orbit-bound microtubules surround the cell cortex, whereas dynamic microtubules with Orbit-decorated plus ends probe the lamella by extending along actin filaments. (b) Dynamic microtubules coalesce during directed migration to form the bundled microtubule arm that becomes Orbit bound over the entire filament length. (c and d) Upon collision with another cell, there is initial alignment of the actin cytoskeletons (c), followed by microtubule arms colliding at the site of cell–cell contact (d). (e and f) Subsequently, microtubules are depolymerized in the vicinity of the cell–cell contact site (e), leading to cellular repolarization and contact repulsion (f).

during migration (Stramer et al., 2005). There is no doubt that our ability to examine these processes in a genetically tractable organism such as Drosophila will greatly aid in the dissection of the molecular events downstream of microtubules during persistent migration and contact repulsion in vivo.

Materials and methods

Fly stocks

For microtubule labeling, the N-terminal 350 aa of human CLIP170 (Perez et al., 1999) were tagged with GFP and mCherry at the N terminus and cloned into pUASP with S' KpnI–NotI and 3' NotI–BamHI sites. To visualize actin, srp-Gal4 (on the second chromosome; Halfon et al., 2002) that allowed us to select for homozygous srp-Gal4, UAS-GFP-Moesin; UAS-Spastin-GFP (Jankovics and Brunner, 2006). To visualize the actin cytoskeleton specifically in hemocytes and visualize the actin cytoskeleton, fly lines were generated expressing srp-Gal4, UAS-GFP-Moesin; UAS-mCherry-CLIP170. To depolymerize the microtubule cytoskeleton in Spastin-expressing and mutant embryos. Video 1 is a 3D reconstruction of hemocytes expressing mCherry-CLIP170 and GFP-Moesin, which label microtubules and actin, respectively. Video 2 is a spinning disk confocal video of a hemocyte with fluorescently labeled actin and microtubules, revealing the colocalization of these two cytoskeletal components and the bundling of microtubules. Video 3 shows a confocal sequence of a hemocyte responding to a laser wound and reveals the time course of microtubule and lamellae dynamics upon consequent repolarization of this cell. Video 4 shows GFP-Moesin–labeled hemocytes undergoing contact repulsion during their embryonic migrations. Video 5 shows a confocal series of actin– and microtubule–labeled hemocytes colliding within the embryo and reveals the transient alignment of the cells’ microtubule bundles upon contact. Video 6 shows a collision between two hemocytes, revealing lamellar contact occurring...
immediately before microtubule alignment and subsequent repolarization. Video 7 shows wild-type versus Spastin-expressing hemocytes as they disperse within the embryo and reveals that cells clump without microtubules. Video 8 shows a confocal series of wild-type versus
