Introduction

During macroautophagy (subsequently referred to simply as autophagy), subcellular membranes undergo dynamic morphological changes that lead to the engulfment and degradation of cellular proteins and cytoplasmic organelles (Maiuri et al., 2007; Levine and Kroemer, 2008). Disruption of autophagic pathways is associated with multiple disease states, including neurodegenerative diseases, cancer, infection, and several types of myopathy (Levine and Kroemer, 2008; Livesey et al., 2009). Autophagy is also a major mechanism by which starving cells reallocate nutrients from unnecessary to more essential processes (Levine and Kroemer, 2008). During autophagy, a cytosolic form of light chain 3 (LC3; LC3-I) is cleaved and then conjugated to phosphatidylethanolamine to form the LC3-phosphatidylethanolamine conjugate (LC3-II), which is recruited to autophagosomal membranes. Detecting microtubule-associated protein LC3 by immunoblotting or immunofluorescence has become a widely used method for monitoring autophagy and autophagy-related processes (Mizushima and Yoshimori, 2007).

Autophagy clears long-lived proteins and dysfunctional organelles and generates substrates for adenosine triphosphate production during periods of starvation and other types of cellular stress. Here we show that high mobility group box 1 (HMGB1), a chromatin-associated nuclear protein and extracellular damage-associated molecular pattern molecule, is a critical regulator of autophagy. Stimuli that enhance reactive oxygen species promote cytosolic translocation of HMGB1 and thereby enhance autophagic flux. HMGB1 directly interacts with the autophagy protein Beclin1 displacing Bcl-2. Mutation of cysteine 106 (C106), but not the vicinal C23 and C45, of HMGB1 promotes cytosolic localization and sustained autophagy. Pharmacological inhibition of HMGB1 cytoplasmic translocation by agents such as ethyl pyruvate limits starvation-induced autophagy. Moreover, the intramolecular disulfide bridge (C23/45) of HMGB1 is required for binding to Beclin1 and sustaining autophagy. Thus, endogenous HMGB1 is a critical pro-autophagic protein that enhances cell survival and limits programmed apoptotic cell death.

Endogenous HMGB1 regulates autophagy

Figure 1. Autophagy promotes extranuclear HMGB1 translocation and is dependent on ROS generation. (A) HMGB1 translocates from the nucleus to the cytosol during autophagy, but not apoptosis. Mouse embryonic fibroblasts (MEFs) and the human Panc2.03 tumor cell line were treated with 1 µM rapamycin (Rap) for 12 h, starvation (HBSS) for 3 h, or UV irradiation at 50 mJ/cm² for 5 min before a 12-h recovery and then were immunostained with HMGB1-specific antibody (green) and Hoechst 33342 (blue). The mean nuclear (Nuc) and cytosolic (Cyt) HMGB1 intensity per cell was determined by imaging cytometric analysis as described in Materials and methods. *, P < 0.05 and **, P < 0.005 versus untreated (UT) group; n = 3. Representative images are depicted (right). (B) Inhibition of autophagy blocks HMGB1 translocation. Cells were pretreated as indicated with 100 nM wortmannin or 10 µM Ly294002 for 1 h or ATG5-specific shRNA for 48 h and were stimulated with starvation (HBSS) for 3 h and immunostained with HMGB1- or LC3-specific antibody and Hoechst 33342. The mean nuclear/cytosolic HMGB1 intensity and LC3 punctae per cell were determined by imaging cytometric analysis. A representative Western blot of ATG5 level after shRNA and HMGB1 staining is depicted (right). In parallel, the indicated cells were transfected with GFP-LC3 plasmid and assayed for autophagy by quantifying the percentage of cells with GFP-LC3 punctae. *, P < 0.05, **, P < 0.005, and ***, P < 0.0005 versus HBSS group; n = 3. Ctrl, control. (C) Knockdown of ATG5 inhibits LC3-II expression. Western blot analysis of LC3-I/II expression in Panc02 cells under the conditions described in B. Actin was used as a loading control. (D) Hmgb1−/− does not influence ATG5 staining. Hmgb1−/− and Hmgb1+/+ MEFs were immunostained with HMGB1-specific antibody (green), ATG-5-specific antibody (red), and Hoechst 33342 (dark blue). Representative images are depicted in the right panels. (E) mETC inhibitors promote ROS production, autophagy, and HMGB1 translocation. Panc2.03 cells were stimulated with rotenone (Rot), thenoyltrifluoroacetone (TTFA), and antimycin A (AA) at indicated doses for 12 h, and ROS production was assessed by measuring the
Although substantial information exists about HMGB1 in the setting of apoptosis and necrosis, the role of HMGB1 in autophagy is essentially uncharacterized. Here we demonstrate that HMGB1 is a critical regulator of autophagy, as HMGB1 translocation induces autophagy after prolonged cellular stress. Interestingly, HMGB1 translocation requires a redox-dependent signal. Moreover, targeted ablation of HMGB1 increases apoptosis and inhibits autophagy by sustaining the interaction between Beclin1 and Bcl-2. Mutation of cysteine 106 (C106), but not the vicinal C23 and C45, of HMGB1 promotes cytosolic localization and autophagy. Additionally, the intramolecular disulfide bridge (C23/45) of HMGB1 is required for binding to Beclin1 and induction of autophagy. These findings define a new biological function for HMGB1 in promoting cell survival by sustaining autophagy in response to cellular stress.

Results

Autophagic stimuli promote translocation of HMGB1 to the cytosol

To investigate the role of HMGB1 when cells are exposed to stimuli that promote autophagy, we first analyzed its expression and location. Classical autophagic stimuli, such as starvation (HBSS) or rapamycin treatment, promoted HMGB1 translocation from the nucleus to the cytosol in cultured mouse embryonic fibroblasts (MEFs), human Panc2.03 (Fig. 1 A), and other cell lines, such as mouse Panc02, human HCT116, and mouse RAW264.7 (not depicted). Treatment with rapamycin or starvation induced HMGB1 translocation unaccompanied by measurable lactate dehydrogenase release (Fig. S1), a marker of plasma membrane disruption. This suggests that the HMGB1 translocation, observed during early events with heightened autophagy, is an active process. Furthermore, pretreatment of the MEF and Panc02 cell lines with the nominal broad phosphatidylinositol-3 kinase inhibitors, such as wortmannin and Ly294002, blocked starvation-induced accumulation of LC3 punctae, LC3-II, and HMGB1 translocation (Fig. 1, B and C). Moreover, knockdown of ATG5, a gene product required for the formation of autophagosomes (Levine and Kroemer, 2008), significantly inhibited the number of starvation-induced LC3 punctae, LC3-II expression, and HMGB1 translocation (Fig. 1, B and C). This suggests that autophagic stimuli regulate HMGB1 cytoplasmic translocation. In contrast, there were no significant differences observed in ATG5 staining when comparing Hmgb1−/− and Hmgb1−/− immortalized MEFs (Fig. 1 D), consistent with the notion that ATG5 is not downstream of HMGB1.

Lack of HMGB1 limits autophagy

To assess the role of HMGB1 in autophagy, we first evaluated autophagic flux in wild-type and Hmgb1−/− MEFs. Hmgb1−/− MEFs had markedly diminished LC3-GFP punctae, endogenous LC3 punctae formation, and LC3-II expression in cells after treatment with several autophagic stimuli, including H2O2, rapamycin, and starvation (Fig. 2, A–C). Treatment with the lysosomal protease inhibitors pepstatin or E64D (Mizushima and Yoshimori, 2007) induced a further increase in LC3-GFP punctae and LC3-II expression in wild-type, but not Hmgb1−/−, MEFs (Fig. 2 C). Similarly, knockdown of HMGB1 in HCT116 and Panc2.03 cells also decreased accumulation of LC3 punctae.

Reactive oxygen species (ROS)-dependent signals are required for HMGB1 translocation and enhanced autophagy

ROS are signaling molecules important in several pathways that regulate both cell survival and cell death. Indeed, many stimuli that induce ROS generation, such as nutrient starvation, mitochondrial toxins, and hypoxia, also induce autophagy (Fig. S2). ROS formation in the mitochondria is a fundamental regulatory event that promotes autophagy (Scherz-Shouval and Elazar, 2007). The major source of endogenous ROS is the mitochondrial electron transport chain (mETC; Scherz-Shouval and Elazar, 2007).

To evaluate the relationship between mitochondrial ROS production and HMGB1 translocation during autophagy, we treated cells with several different mETC inhibitors. Treatment with rotenone (Rot; complex I inhibitor), thenoyltrifluoroacetone (complex II inhibitor), and antimycin A (complex III inhibitor) increased ROS production, LC3 punctae, and LC3-II expression (Fig. 1, E and F). These mETC inhibitors also induced HMGB1 translocation from the nucleus to the cytosol, as assessed by imaging cytometry and Western blot of subcellular fractions (Fig. 1, E and F). Under physiological conditions, ROS are cleared from cells by the action of the superoxide dismutase (SOD) family members, catalase, or glutathione peroxidase (Scherz-Shouval and Elazar, 2007). As expected, knockdown of SOD1 and SOD2 increased starvation- and rapamycin-induced autophagy and HMGB1 translocation in Panc2.03 cells (Fig. 1, G and H; and Fig. S3). Furthermore, N-acetyl cysteine (NAC), an ROS quencher, dose-dependently inhibited starvation- and rapamycin-induced autophagy and HMGB1 translocation (Fig. 1, G and H; and Fig. S3). Moreover, starvation and rapamycin increased ROS/mitochondrial superoxide levels and decreased SOD activity but did not affect catalase activity or detected levels (Fig. S2). Together, these results are consistent with the notion that ROS signals are required for HMGB1 translocation and sustained autophagy.

Fluorescent intensity of CM-H2DCFDA in a fluorescent plate reader. In parallel experiments, cells were then immunostained with HMGB1- or LC3-specific antibody and Hoechst 33342. The mean nuclear/cytosolic HMGB1 intensity and LC3 punctae per cell were determined by imaging cytometric analysis. *, P < 0.05; **, P < 0.005; and ***, P < 0.0005 versus untreated group; n = 3. [H] Antioxidant and SOD RNAi limit starvation-induced autophagy and HMGB1 translocation. Panc2.03 cells were pretreated with the antioxidant (NAC) at the indicated concentrations for 1 h or with SOD1 or SOD2 siRNA for 48 h. Then cells were starved (HBSS) for 3 h and analyzed by imaging cytometry to determine the mean nuclear/cytosolic HMGB1 intensity and LC3 punctae per cell. *, P < 0.05; **, P < 0.005; and ***, P < 0.0005 versus HBSS group; n = 3. A representative Western blot for SOD1 and SOD2 level after siRNA is depicted here.

885HMGB1 regulates autophagy • Tang et al.

Under normal conditions, 5–10% of HMGB1 protein is located in the cytosol, with the specific quantity dependent on the cell type (Fig. 1 A and Fig. 3 A). Moreover, autophagic stimuli promote translocation of HMGB1 to the cytosol (Fig. 1 A and Fig. 3 A). To assess the role of cytoplasmic HMGB1 in the setting of autophagy, we created cytoplasts (anucleate cells). In response to starvation (HBSS), Hmgb1+/+ MEF cytoplasts were still able to accumulate LC3 punctae (Fig. 3, A and B; and expression of LC3-II (Fig. S4). Moreover, up-regulation of HMGB1 expression in Hmgb1−/− MEFs after gene transfection restored LC3 punctae formation (Fig. 2 D). Inhibition of autophagy leads to an increase in the size and number of p62 bodies and p62 protein levels (Bjørkøy et al., 2005). Loss of HMGB1 increases the size and number of p62 bodies and p62 protein levels (Fig. 2 E), indicating that its degradation is dependent on HMGB1-mediated autophagy. Ultrastructural analysis revealed that Hmgb1−/− MEFs exhibited fewer type I autophagosomes and type II autophagolysosomes when compared with wild-type MEFs (Fig. 2 F). These results indicate that HMGB1 is indeed an important factor that regulates autophagy.

Under normal conditions, 5–10% of HMGB1 protein is located in the cytosol, with the specific quantity dependent on the cell type (Fig. 1 A and Fig. 3 A). Moreover, autophagic stimuli promote translocation of HMGB1 to the cytosol (Fig. 1 A and Fig. 3 A). To assess the role of cytoplasmic HMGB1 in the setting of autophagy, we created cytoplasts (anucleate cells). In response to starvation (HBSS), Hmgb1+/+ MEF cytoplasts were still able to accumulate LC3 punctae (Fig. 3, A and B;
Bcl-2 and Beclin1. The MAPK kinase (MEK)/extracellular signal-regulated kinase (ERK) inhibitors PD98059 and U0126 inhibited starvation-induced phosphorylation of ERK (p-ERK1/2) and Bcl-2 (Fig. 4 A). Moreover, knockout of HMGB1, as well as addition of the MEK/ERK inhibitor U0126, blocked the dissociation of Bcl-2–Beclin1 in the setting of enhanced autophagy (Fig. 4, B and F), suggesting that ERK1/2-mediated phosphorylation of Bcl-2 regulates starvation-induced autophagy. When present, endogenous HMGB1 demonstrated an interaction with Beclin1 by coimmunoprecipitation (IP [co-IP]) assay in MEFs, HCT116, and Panc02 cells (Fig. 4, B, C, and E). Knockdown of Beclin1 inhibited the interaction between Bcl-2 and HMGB1 in untreated HMGB1 wild-type MEFs (Fig. 4, B and D), suggesting that HMGB1 interaction with Bcl-2 is directly dependent on Beclin1. Thus, via binding to Beclin1 and regulating the phosphorylation of Bcl-2 in cells after starvation, endogenous HMGB1 inhibits the interaction between Beclin1 and Bcl-2.

**Oxidation of HMGB1 regulates autophagic flux**

Oxidation of the three cysteines found within HMGB1 is important to its function (Hoppe et al., 2006; Kazama et al., 2008). In contrast, Hmgb1−/− MEF cytoplasts demonstrated a lower level of LC3 punctae than HMGB1+/+ (Fig. 3, A and B), indicating that cytoplasmic HMGB1 was required for starvation-stimulated autophagy.

Both starvation and rapamycin treatment enhance autophagy and induce apoptosis in some cell lines (Maiuri et al., 2007). We therefore evaluated the relationship between HMGB1 and apoptosis under these conditions. Increased apoptosis was observed in Hmgb1−/− MEFs when compared with wild-type cells by flow cytometry using an annexin V stain, by finding increased cleaved poly(ADP-ribose) polymerase (PARP), and by increased caspase-3 activation (Fig. S5). Collectively, these data suggest that HMGB1 plays a major role in promoting autophagy and limiting apoptosis.

**Depletion of HMGB1 promotes persistent Beclin1–Bcl-2 interaction**

An important molecular event observed during autophagy is the dissociation of the Bcl-2–Beclin1 complex (Pattingre et al., 2005). The Bcl-2 family of antiapoptotic proteins regulates Beclin1-dependent autophagy (Pattingre et al., 2005). Thus, we determined the effect of HMGB1 on the interaction between Bcl-2 and Beclin1. The MAPK kinase (MEK)/extracellular signal-regulated kinase (ERK) inhibitors PD98059 and U0126 inhibited starvation-induced phosphorylation of ERK (p-ERK1/2) and Bcl-2 (Fig. 4 A). Moreover, knockout of HMGB1, as well as addition of the MEK/ERK inhibitor U0126, blocked the dissociation of Bcl-2–Beclin1 in the setting of enhanced autophagy (Fig. 4, B and F), suggesting that ERK1/2-mediated phosphorylation of Bcl-2 regulates starvation-induced autophagy. When present, endogenous HMGB1 demonstrated an interaction with Beclin1 by communoprecipitation (IP [co-IP]) assay in MEFs, HCT116, and Panc02 cells (Fig. 4, B, C, and E). Knockdown of Beclin1 inhibited the interaction between Bcl-2 and HMGB1 in untreated HMGB1 wild-type MEFs (Fig. 4, B and D), suggesting that HMGB1 interaction with Bcl-2 is directly dependent on Beclin1. Thus, via binding to Beclin1 and regulating the phosphorylation of Bcl-2 in cells after starvation, endogenous HMGB1 inhibits the interaction between Beclin1 and Bcl-2.
cytoplasmic translocation by ethyl pyruvate (Ulloa et al., 2002) and blocked starvation-induced aggregation of LC3 punctae (Fig. 5 B), suggesting that cytoplasmic HMGB1 regulates autophagy. Consequently, transfection of wild-type HMGB1 and the C106S variant, but not the mutant C23S or C45S plasmids that are localized to the nucleus, up-regulated autophagy and down-regulated apoptosis in Hmgb1−/− MEFs (Fig. 5, B and C). The HMGB1 C106S mutation increased the dissociation of Bcl-2 and Beclin1 and promoted p-ERK1/2 and Bcl-2 in HMGB1−/− cells after starvation (Fig. 5 D). The C23S and C45S variants, but not those with the C106S mutation, impaired the interaction between HMGB1 and Beclin1 and the p-ERK1/2 and Bcl-2 (Fig. 5 D), suggesting that the intramolecular disulfide bridge (C23/45) is required for binding to Beclin1. To further confirm this hypothesis, we applied a reducing reagent (DTT) during the IP experiments. As expected, samples treated with DTT (Fig. 5 E, +DTT) before IP disrupted the interaction between wild-type/C106 HMGB1 and Beclin1. As a control, before IP, samples were incubated with 50 mM DTT (+DTT) and assayed for protein expression levels as indicated by IP or Western blotting. Blots are representative of three independent experiments with similar results. Knockdown of Beclin1 by siRNA inhibits autophagy under conditions of HMGB1 translocation from the nucleus to the cytosol. Cells were stimulated with HBSS, rapamycin (Rap), rotenone (Rot), or thenoyltrifluoroacetone (TTFA) for 3 h or 12 h, and LC3 punctae formation was assayed as indicated. **, P < 0.005 versus Beclin1 shRNA group; n = 3. Ctrl, control. Data are means ± SEM.

These cysteines are encoded at positions 23, 45, and 106 (C23, C45, and C106, respectively; Fig. 5 A). Under mild oxidative conditions, the vicinal cysteines C23 and C45 readily form an intramolecular disulfide bridge, whereas C106 remains in a reduced form (Hoppe et al., 2006). Blocking sites of oxidation in HMGB1 prevents the induction of tolerance by apoptotic cells (Kazama et al., 2008). Transfection of the constitutively active redox sensor HMGB1-GFP-C106 mutation (C106S) into HMGB1 knockout cells impaired nuclear localization of HMGB1, which increases cytoplasmic aggregation of HMGB1 (Fig. 5 A; Hoppe et al., 2006) and LC3 punctae formation (Fig. 5 B). This suggests that the C106 of HMGB1 may play a role in regulating its intracellular translocation and, subsequently, autophagy. Moreover, autophagic stimuli (rapamycin or starvation) promoted translocation of wild type as well as mutant C23S, C45S, and C106S HMGB1 into the cytosol (Fig. 5 A). Inhibition of HMGB1 cytoplasmic translocation by ethyl pyruvate (Ulloa et al., 2002) blocked starvation-induced aggregation of LC3 punctae (Fig. 5 B), suggesting that cytoplasmic HMGB1 regulates autophagy. Consequently, transfection of wild-type HMGB1 and the C106S variant, but not the mutant C23S or C45S plasmids that are localized to the nucleus, up-regulated autophagy and down-regulated apoptosis in Hmgb1−/− cells after starvation (Fig. 5, B and C). The HMGB1 C106S mutation increased the dissociation of Bcl-2 and Beclin1 and promoted p-ERK1/2 and Bcl-2 in HMGB1−/− cells after starvation (Fig. 5 D). The C23S and C45S variants, but not those with the C106S mutation, impaired the interaction between HMGB1 and Beclin1 and the p-ERK1/2 and Bcl-2 (Fig. 5 D), suggesting that the intramolecular disulfide bridge (C23/45) is required for binding to Beclin1. To further confirm this hypothesis, we applied a reducing reagent (DTT) during the IP experiments. As expected, samples treated with DTT (Fig. 5 E, +DTT) before IP disrupted the interaction.
factors. Highly integrated and stereotypic response patterns are found in many organisms, but the means by which so many diverse pathways, critical for cellular, tissue, and ultimately organismal survival, are coordinated has yet to be elucidated. Here, we show that depletion of the evolutionarily ancient and highly conserved HMGB1 protein inhibits autophagy in human and murine cells. Conversely, inhibition of autophagy limits HMGB1 translocation, suggesting that HMGB1 is central to the regulation of autophagy. Moreover, we have shown that this effect is controlled by ERK1/2 phosphorylation and by interrupting the interaction of Beclin1 with Bcl-2. HMGB1 C106 is important for its translocation between the nucleus and cytoplasm, and oxidized C23/45 is required for the binding to Beclin1. These findings have implications for the temporal and spatial regulation of HMGB1 within cells and tissues, the connection between HMGB1 and autophagic pathways, and the role of HMGB1 as a critical regulator of cell survival.

HMGB1 protein is both a nuclear DNA binding factor and a secreted protein that is critically important for cell death and survival (Tang et al., 2010b). Its activities are determined by its intracellular localization and posttranslational modifications (including acetylation, ADP-ribosylation, phosphorylation, and thiol oxidation; Scaffidi et al., 2002; Lotze and Tracey, 2005; Hoppe et al., 2006; Kazama et al., 2008). HMGB1 is released during necrosis as an endogenous damage-associated molecular pattern molecule, or “danger” signal, during cell death (Scaffidi et al., 2002). Late-stage apoptotic cells can indeed release HMGB1, and oxidation of HMGB1 interferes with its ability to promote immunity (Kazama et al., 2008). ROS also function between wild-type/C106S HMGB1 and Beclin1. Furthermore, siRNA knockdown of Beclin1 inhibited autophagy under conditions that induce HMGB1 translocation from the nucleus to the cytosol, such as H2O2, rapamycin, Rot, thienofluoroacetone, and HBSS (Fig. 5 F). Moreover, knockdown of Beclin1 inhibited autophagy induced by treatment with exogenous HMGB1 and overexpression of HMGB1 with or without starvation, suggesting that Beclin1 was required for HMGB1-mediated autophagy (Fig. 6, A–D).

To further confirm that oxidation of HMGB1 regulates autophagic flux, we analyzed the colocalization of lysosomal-associated membrane protein 2 (LAMP2) and LC3 in the presence or absence of bafilomycin A1, an inhibitor of autophagic vacuole and lysosome function. Bafilomycin A1 decreased LAMP2/LC3 colocalization after starvation-mediated autophagy in wild-type MEFs (Fig. 7, A and B). Moreover, expression of HMGB1 or the C106S mutant, but not the C23S and C45S mutants, restored autophagic flux in Hmgb1−/− MEFs (Fig. 7, A and B).

Together, these findings demonstrate that oxidation of HMGB1 promotes its localization to the cytosol and subsequent induction of autophagy (Fig. 8). Our findings also suggest that cytoplasmic translocation of HMGB1 is necessary, but may not be sufficient, to promote and sustain autophagy.

Discussion

The response of multicellular organisms to stress and maintenance of tissue homeostasis is a common biological problem in all eukaryotes, dictated by both genetic and environmental factors. Highly integrated and stereotypic response patterns are found in many organisms, but the means by which so many diverse pathways, critical for cellular, tissue, and ultimately organismal survival, are coordinated has yet to be elucidated. Here, we show that depletion of the evolutionarily ancient and highly conserved HMGB1 protein inhibits autophagy in human and murine cells. Conversely, inhibition of autophagy limits HMGB1 translocation, suggesting that HMGB1 is central to the regulation of autophagy. Moreover, we have shown that this effect is controlled by ERK1/2 phosphorylation and by interrupting the interaction of Beclin1 with Bcl-2. HMGB1 C106 is important for its translocation between the nucleus and cytoplasm, and oxidized C23/45 is required for the binding to Beclin1. These findings have implications for the temporal and spatial regulation of HMGB1 within cells and tissues, the connection between HMGB1 and autophagic pathways, and the role of HMGB1 as a critical regulator of cell survival.
neutrophils and in ischemic tissues, including hepatocytes (Tang et al., 2007c; Tsung et al., 2007).

These findings (Fig. 2 and Fig. 3) suggest that HMGB1 is directly involved in the positive regulation and maintenance of autophagy in stressed cells. Autophagy was first discovered as a nonselective pathway for the degradation of intracellular constituents, activated in response to starvation (Maiuri et al., 2007; Levine and Kroemer, 2008). It is now clear that selective autophagic degradation of specific organelles and proteins occurs in response to diverse stimuli, varying from survival-promoting removal of pathogens, to degradation of damaged organelles and proteins, to programmed cell survival or cell death (Scherz-Shouval and Elazar, 2007). We found that targeted as signaling molecules in various pathways regulating both cell survival and cell death. ROS can induce autophagy through several distinct mechanisms involving catalase activation of Atg4 and disturbances in the mETC (Scherz-Shouval et al., 2007). We have shown here that ROS generated during starvation and rapamycin treatment serve as signaling molecules that initiate autophagy. Importantly, these stimuli caused HMGB1 cytosolic translocation from the nucleus, indicating that the function and localization of HMGB1 necessary to enhance autophagy are different from that observed in apoptosis. Moreover, we have demonstrated that HMGB1 translocation in autophagy is ROS dependent. Indeed, oxidative stress regulates HMGB1 release and subsequent inflammation in recruited macrophages and

Figure 7. Expression of HMGB1 or the C106S mutant, but not C23S and C45S mutants, restore autophagic flux in Hmgb1−/− MEfS. (A) Hmgb1−/− MEfS were transfected with wild-type (WT) or the cysteine mutant HMGB1-GFP plasmids as indicated, starved (HBSS) for 3 h in the presence or absence of 100 nM bafilomycin A1, and then immunostained with LAMP2-specific antibody/Alexa Fluor 594 secondary antibody (shown in red), LC3-specific antibody/Alexa Fluor 647 secondary antibody (shown in green), and Hoechst 33342 (shown in blue). Images were acquired digitally from a randomly selected pool of 10–15 fields under each condition. (B) Quantitative analysis of the percentage of LAMP2/LC3 colocalization was detected by Image-Pro Plus 5.1 software. Data are means ± SEM.
deletion of HMGB1 limits starvation-induced autophagy and enhances apoptosis. In the setting of cancer, overexpression of HMGB1 is associated with aberrant survival of many types of cancer, including breast, colon, melanoma, and others (Tang et al., 2010b). Thus, HMGB1 plays an important role in the regulation of autophagy in response to metabolic stress, oxidative injury, and genomic instability promoting programmed cell survival.

This study demonstrates that HMGB1 promotes and sustains autophagy, and we explored the mechanism by which this occurs. HMGB1 confers pro-autophagic activities, likely by controlling Beclin1–Bcl-2 complex formation. The dissociation of Bcl-2 from Beclin1 is an important mechanism involved in activating autophagy and limiting apoptosis in response to starvation and potentially after other physiological stimuli (Pattingre et al., 2005). Before this study, the regulation of the interaction between Bcl-2 and Beclin1 by adverse nutrient conditions was not thoroughly explored. We found that HMGB1 disrupts the interaction between Beclin1 and Bcl-2 by competitively binding to Beclin1 after starvation. The oxidation-sensitive C106, but not the vicinal C23 and C45, of HMGB1 regulated cytosolic localization and autophagy. C106S mutants have much higher cytoplasmic levels of HMGB1 and demonstrate enhanced binding to Beclin1, leading to the subsequent dissociation of Bcl-2 from Beclin1. C106S mutants were capable of initiating starvation-induced autophagy as efficiently as wild-type HMGB1, whereas C23S and C45S mutations abolished this effect. Thus, in two independent experiments, C106S mutants behave in a similar fashion to wild-type HMGB1. Meanwhile, C23S and C45S mutants lose their ability to mediate autophagy, as they are unable to bind Beclin1 and, therefore, cannot disrupt Bcl-2–Beclin1 interactions. These findings demonstrate that oxidation of HMGB1 regulates its localization and ability to sustain autophagy (Fig. 6).

It thus appears that cytoplasmic translocation of HMGB1 is necessary but may not be sufficient to enhance autophagy.

The antiapoptotic molecule Bcl-2 is involved in the regulation of cell death and survival pathways during apoptosis and autophagy. It was previously reported that the phosphorylation of Bcl-2, likely by kinases of the JNK or ERK signaling pathway, is required for its antiapoptotic activity (Subramanian and Shah, 2007; Wei et al., 2008). Our findings suggest that HMGB1 may also be involved in the regulation of Bcl-2 phosphorylation by the ERK/MAPK pathway because ablation of HMGB1 diminishes starvation-induced phosphorylation of both ERK1/2 and Bcl-2, although the mechanism of this effect is not clear. A recent study has shown that the HMGB1 receptor, receptor for advanced glycation endproducts, directly binds to ERK through a D domain–like docking site and regulates p-ERK1/2 (Ishihara et al., 2003). It is possible that cytoplasmic HMGB1 interacts with the cytosolic domain of receptor for advanced glycation endproducts and mediates concomitant ERK1/2 and Bcl-2 phosphorylation.

Based on the work reported here and previous findings implicating the nuclear sequestration of HMGB1 in apoptosis, its extracellular release in inflammation (Wang et al., 1999; Scaffidi et al., 2002; Kazama et al., 2008), and its critical role as a universal DNA sensor (Yanai et al., 2009; Sims et al., 2010), we propose a more nuanced conceptual model involving HMGB1 and cell death. In this model, ROS generated by cellular stress promote HMGB1 translocation to the cytosol, which induces autophagy, enhancing ERK signaling and disrupting Beclin1–Bcl-2 complex formation (Fig. 6). Thus, endogenous HMGB1 plays a central role in regulating programmed cell death (apoptosis) and programmed cell survival (autophagy). These findings will be instrumental in developing more effective therapies in the context of chronic inflammatory diseases, some of them associated with release of damage-associated molecular proteins (Zhang et al., 2010), including neurodegenerative disorders, autoimmunity, and cancer.

**Materials and methods**

**Reagents**

The antibodies to HMGB1 were obtained from Sigma-Aldrich and Novus Biologicals. The antibodies to caspase-3, cleaved caspase-3, cleaved PARP, GFP, Bcl-2, p-ERK (Thr202/Tyr204), and ERK were obtained from Cell Signaling Technology. The antibodies to tubulin and actin were obtained from Sigma-Aldrich. The antibodies to phosphoserine, SOD1, SOD2, fibrillarin, and catalase were obtained from Abcam. The antibodies to AFG5 and Beclin1 were purchased from Novus Biologicals. The antibody to LC3 was purchased from Novus Biologicals or AnaSpec. The antibody to p62 was obtained from Santa Cruz Biotechnology, Inc. The SOD activity assay kit was also obtained from Abcam. The nuclear and cytoplasmic extraction kit was obtained from Thermo Fisher Scientific. Other reagents and kits were obtained from Sigma-Aldrich.

**Cell culture**

Panc2.03, Panc02, HCT116, and Hmgb1−− and Hmgb1++ immortalized MEF [Scaffidi et al., 2002] cells were cultured in RPMI 1640, DMEM, or McCoy’s 5a medium supplemented with 10% heat-inactivated FBS, 2 mM glutamine, and antibiotic–antifungal mix (10,000 units/ml penicillin and 10,000 µg/ml streptomycin; Invitrogen) in a humidified incubator with 5% CO2.

**Gene transfection and RNAi**

HMGB1-GFP or mutant (C23S, C45S, or C106S; Hoppe et al., 2006) or pUNO1-HMGB1 (InvivoGen) expression vectors were transfected into cells...
using Lipofectamine 2000 reagent (Invitrogen) according to the manufacturer’s instructions. Constructs were sequenced and confirmed in the University of Pittsburgh core sequencing laboratories. Human SOD1/SOD2-siRNA, mouse Beclin1–Bcl-2 siRNA (Santa Cruz Biotechnology, Inc.), mouse Beclin1 short hairpin RNA (shRNA), human HMGB1 shRNA, and mouse ATG5 shRNA (Sigma-Aldrich) were transfected into cells using Lipofectamine RNAiMAX reagent (for siRNA) or Lipofectamine 2000 reagent (for shRNA) according to the manufacturer’s instructions (Invitrogen). After transfection and transfection and RNAi for 48 h, the medium over the cells was changed before subsequent treatments.

Western blotting
Whole-cell lysates were resolved on 4–12% Criterion XT Bis-Tris gels (Bio-Rad Laboratories) and transferred to a nitrocellulose membrane as previously described (Tang et al., 2007b). After blocking, the membrane was incubated for 2 h at 25°C or overnight at 4°C with various primary antibodies. After incubation with peroxidase-conjugated secondary antibodies for 1 h at 25°C, the signals were visualized by enhanced chemiluminescence (Thermo Fisher Scientific) according to the manufacturer's instruction. The relative band intensity was quantified using the Gel-pro Analyzer software (Media Cybernetics).

Measurement of intracellular ROS and mitochondrial superoxide
Cells were seeded in 96-well plates and cultured in the presence of a given stimulus for indicated time. ROS were assayed with cell-permeant dyes CM-H2DCFDA (Invitrogen) and mitochondrial superoxide using MitoSox (Invitrogen) as described previously (Kang et al., 2010b). Analysis of signal intensity was performed using a fluorescence plate reader.

IP analysis
Cells were lysed at 4°C in ice-cold radioimmunoprecipitation assay lysis buffer (Millipore), and cell lysates were cleared by a brief centrifugation for 10 min at 12,000 g. Concentrations of proteins in the supernatant were determined by bicinchoninic acid assay. Before IP, samples containing equal amounts of proteins were precleared with protein A or protein G agarose Sepharose at 4°C for 3 h and subsequently incubated with 2–5 μg/ml various irrelevant IgG or specific antibodies in the presence of protein A or G agarose/Sepharose beads for 2 h or overnight at 4°C with gentle shaking (Tang et al., 2007a,b). After incubation, agarose/Sepharose beads were washed extensively with PBS, and proteins were eluted by boiling in 2x SDS sample buffer before SDS-PAGE electrophoresis. As a control, a portion of the lysate was treated with 50 mM DTT to reduce sample as described previously (Anathy et al., 2009).

Analysis of HMGB1 translocation and LC3 punctae formation by imaging cytometry
Cells were seeded in 96-well plates, cultured in the presence of various stimuli for given times, and then fixed with 3% paraformaldehyde and stained with HMGB1 or LC3 antibody. Secondary antibodies were goat IgG conjugated either with Alexa Fluor 488 or Alexa Fluor 647 fluorochromes. Nuclear morphology was visualized with the fluorescent dye Hoechst 33342 (Sigma-Aldrich). Imaging data were collected with an imaging cytometer (ArrayScan HCS 4.0, Cellomics) with a 20× objective at 25°C. The ArrayScan is an automated fluorescent imaging microscope that collects information about the spatial distribution of fluorescently labeled components in cells placed in 96-well microtiter plates. The Spot Detector BioApplication (Thermo Fisher Scientific) was used to acquire and analyze the images after optimization. Images of 500–1,000 cells for each treatment group were analyzed to obtain the mean nuclear and cytosolic HMGB1 intensity and LC3 fluorescence punctae number per cell (Tang et al., 2009).

Autophagy assays
All assays for endogenous LC3 punctae were performed by imaging cytometry as previously described (Kang et al., 2010a). Formation of autophagic vesicles was further monitored by transient expression of GFP-LC3 (gifts of X.-M. Yin, University of Pittsburgh, Pennsylvania, PA) aggregation in cell lines. The percentage of cells with GFP-LC3 punctae was determined by counting the number of positively staining cells from 100 randomly chosen cells from three separate experiments. Autophagic flux assays were performed by Western blotting for LC3-II formation after starvation in the presence or absence of lysosomal protease inhibitors (E64d/pepstatin A) as recommended (Mizushima and Yoshimori, 2007).

Confocal microscopy analysis of p62 and colocalization of LAMP2/LC3 were performed. Images were collected using a laser-scanning confocal microscope (Fluoview FV-1000; Olympus) using a 60× Plan Apo/1.45 oil immersion objective at 25°C and were captured and analyzed by Fluoview software (FV10-ASW 1.6; Olympus). Images were subsequently analyzed for the level and colocalization by Image-Pro Plus 5.1 software (Media Cybernetics).

Transmission electron microscopy assessment of autophagosome and autophagolysosomes was performed as previously described (Shao et al., 2004). In brief, cells were fixed with 2% paraformaldehyde and 2% glutaraldehyde in 0.1 mol/L phosphate buffer, pH 7.4, followed by postfixation for 6 h in 1% O3O4. After dehydration with graded alcohols, the samples were embedded in epoxy resin (epon). Then, thin sections (70 nm) were cut with a microtome (Ultracut R; Leica), mounted on copper grids and poststained with 2% uranyl acetate and 1% lead citrate, dried, and analyzed using a transmission electron microscope at 25°C (100CX; JEOL, Inc.). Thick sections were cut (300 nm) and stained with 1% toluidine blue. Images were acquired digitally from a randomly selected pool of 10–15 fields under each condition.

Apoposis assays
Autophagy in cells was assessed using the FITC Annexin V Apoptosis Detection kit (BD; annexin-V-FITC, propidium iodide (PI) solution, and annexin V binding buffer). This assay involves staining cells with annexin V-FITC (a phospholipid-binding protein that binds to disrupted cell membranes) in combination with PI (a vital dye that binds to DNA penetrating into apoptotic cells). Flow cytometric analysis (FACS) was performed to determine the percentage of cells that were undergoing apoptosis (annexin V+/PI–). Cleaved PARP and cleaved caspase-3 were measured by Western blotting analysis.

Enucleation by centrifugation
HMGB1+/− and HMGB1−/− MEFs grown on collagen-coated microcover-slips were enucleated as described previously, with minor modifications (Goldman et al., 1973; Miller and Ruddle, 1974). To enucleate the cells, the microcover-slips were inverted (cell side down) and placed into the bottom of 1.5-ml Eppendorf tubes containing 10 μg/ml cytochalasin B (Sigma-Aldrich) in medium. After centrifugation at 12,000 g for 60 min, the microcover-slips were removed from the tubes and placed cell side up into a 6-well plate containing 2 ml of medium without cytochalasin B for subsequent studies and staining for autophagy.

Statistical analysis
Data are expressed as means ± SEM of three independent experiments performed in triplicate. One-way analysis of variance was used for comparison among the different groups by SPSS 12.0. When the analysis of variance was significant, post-hoc testing of differences between groups was performed using Fisher’s least significant difference test. A p-value <0.05 was considered significant; P < 0.005 and P < 0.0005 were reported where applicable.

Online supplemental material
Fig. S1 shows that autophagic stimuli promote cytosolic HMGB1 translocation that is not dependent on plasma membrane disruption. Fig. S2 shows that autophagic stimuli increase ROS and mitochondrial superoxide levels and decrease SOD activity while having no direct effect on catalase activity levels. Fig. S3 shows that provision of antioxidants or knockdown of SOD1 and SOD2 increases rapamycin-induced autophagy and HMGB1 translocation. Fig. S4 shows that knockdown of HMGB1 limits autophagy in HCT116 and Panc2.03 cells. Fig. S5 shows that provision of antioxidants or knockdown of HMGB1 limits autophagy.
