These data present a collection of subcellular-targeted fluorescent proteins tested for their specificity in zebrafish cells. “mem” represents a membrane localization signal, which consists of a palmitoylation and myristinylation sequence of the human Lck kinase.
The centrosome neither persistently leads migration nor determines the site of axonogenesis in migrating neurons in vivo

Helmholtz Zentrum München German Research Center for Environmental Health, Institute of Developmental Genetics, 85764 Munich-Neuherberg, Germany

The position of the centrosome ahead of the nucleus has been considered crucial for coordinating neuronal migration in most developmental situations. The proximity of the centrosome has also been correlated with the site of axonogenesis in certain differentiating neurons. Despite these positive correlations, accumulating experimental findings appear to negate a universal role of the centrosome in determining where an axon forms, or in leading the migration of neurons. To further examine this controversy in an in vivo setting, we have generated cell type–specific multi-cistronic gene expression to monitor subcellular dynamics in the developing zebrafish cerebellum. We show that migration of rhombic lip–derived neurons is characterized by a centrosome that does not persistently lead the nucleus, but which is instead regularly overtaken by the nucleus. In addition, axonogenesis is initiated during the onset of neuronal migration and occurs independently of centrosome proximity. These in vivo data reveal a new temporal orchestration of organelle dynamics and provide important insights into the variation in intracellular processes during vertebrate brain differentiation.

Introduction

Neuronal progenitors undergo a variety of developmental steps to form a functional brain. After proliferation, they migrate, differentiate terminally, and generate dendrites and axons to establish neuronal circuits. Cell behavior at each step is coordinated by the subcellular organelle dynamics occurring within the developing neurons. The centrosome in particular, through its function as a microtubule-organizing center (MTOC), has been proposed to act as a main organizer of polarized cell behaviors such as directed migration and axonogenesis (Higginbotham and Gleeson, 2007).

Within cells in a proliferating neuroepithelium, the centrosome localizes strictly to the apical (ventricular) side to maintain apico-basal polarity (Hinds and Ruffet, 1971; Shoukimas and Hinds, 1978). During both radial and tangential migration, the apical process of the immature neuron becomes disconnected from the proliferation zone and the cell body advances behind an extended membrane protrusion termed the leading process. Individual migratory steps of neurons are characterized by the forward movement of the nucleus—a process termed nucleokinesis—which can occur in a saltatory manner alternating with resting phases. In most analyzed neurons migrating by saltatory nucleokinesis, the centrosome is localized ahead of the nucleus to face toward the leading process, with the centrosome moving forward before the nucleus (Solecki et al., 2004; Tanaka et al., 2004; Bellion et al., 2005; Schaar and McConnell, 2005; Mélin et al., 2006; Tsai et al., 2007). Due to these observations, a common model for saltatory nucleokinesis in migrating neurons—defined by the sequential subcellular events of a continuously leading centrosome followed by a trailing nucleus—attributes the centrosome with a permanently leading role in initiating and directing migration. (Tsai and Gleeson, 2005; Marín et al., 2006; Higginbotham and Gleeson, 2007; Mélin et al., 2008).

Such an orientation of the centrosome in the direction of cell migration and ahead of the nucleus is not unique to neurons, but is a general phenomenon in many tissues known to use a similar type of movement—saltatory migration. (Solecki et al., 2004; Bellion et al., 2005; Schaar and McConnell, 2005; Mélin et al., 2006; Tsai et al., 2007). This model suggests that the centrosome leads the cell in a directed manner and maintains a leading role throughout development—both in the initiating event of axonogenesis and during the later stages of translocation and axon elongation.
but has been observed in many other cell types during migration, such as endothelial cells (Gotlieb et al., 1981), macrophages (Nemere et al., 1985), and fibroblasts (Kupfer et al., 1982; Schliwa et al., 1999). In non-neuronal migrating cells though, a correlation between migration and a leading centrosome is less consistent. For example, in fibroblasts migrating on grooved substrates or in collagen gels, the centrosome position is randomized with respect to the nucleus and the cell front (Schütze et al., 1991), whereas the centrosome in PtK cells lags behind the nucleus during wound-healing migration (Yvon et al., 2002). Similarly, a centrosome trailing the nucleus has been observed in cells of the migrating lateral line primordium in zebrafish embryos (Pouthas et al., 2008).

Reorientation of the centrosome can be stimulated by molecular interactions or gradients (Nemere et al., 1985; Renaud et al., 2008), electrical stimulation (Pu and Zhao, 2005; Zhao et al., 2006), or shear stress (Coan et al., 1993; Lee et al., 2005). This suggests that centrosome position is strongly influenced by the local molecular composition of the environment, but also by physical and physiological parameters such as morphogenetic constraints and electrical activity. Centrosome orientation may thus vary depending on the cell type, the tissue, and the developmental stage. Strikingly, it was recently shown that in radially migrating granule neurons of the developing cerebellum, the centrosome does not strictly lead migration during salutary nucleokinesis, but it is often overtaken by the nucleus (Umeshima et al., 2007). This centrosomal behavior conflicts with the commonly used model of neuronal nucleokinesis; however, it was suggested that bidirectional movements of the nucleus may be the reason for the unusual temporary trailing of the centrosome in migrating granule neurons (Vallee et al., 2009). Clearly, further in vivo investigations are required to address a potential cell-type dependency of centrosome dynamics during neuronal migration.

An equally important role attributed to the centrosome is the determination of the site of axon outgrowth, as the centrosome is found in close proximity to the neurite that becomes the axon (Zmuda and Rivas, 1998; de Anda et al., 2005). In support, centrosome duplication through inhibition of cytokinesis resulted in two axons emerging adjacent to the centrosomes, whereas laser inactivation of the centrosome in cultured Drosophila neurons impaired axon formation (de Anda et al., 2005). In contrast though, axonogenesis is unaffected in Dsas-4 mutant flies, which are unable to replicate centrioles and therefore lack functional centrosomes by the third instar larval stage (Basto et al., 2006). Additionally, it was recently reported that, at least after axon induction, continued axon outgrowth from hippocampal neurons occurs through centrosome-independent polymerization of microtubule fibers, and is in fact unaffected by laser ablation of the centrosome (Stiess et al., 2010). These controversial observations argue for differences between the cell culture and in vivo situation or suggest that organelle dynamics differ between neuronal cell types. Therefore, an in vivo investigation into the temporal relationship between centrosome dynamics and emerging axonogenesis is needed. Such an approach though, requires a cell type–specific multiple organelle labeling technology.

We have established efficient coactivation of multiple cell biological fluorescent reporter proteins expressed from Gal4-dependent multi-cistronic expression cassettes. In addition, we generated a stable transgenic zebrafish strain expressing the modified Gal4 transcriptional activator KalTA4 (Distel et al., 2009) under the control of regulatory elements from the zebrafish atonal1 gene and thus specifically in neuronal progenitors of the hindbrain rhombic lip. These neurons of the segmental hindbrain nuclei (THN) have been shown to undergo long-distance migration along characteristic pathways through the developing zebrafish cerebellum and into the hindbrain tegmentum in an evolutionarily conserved manner (Köster and Fraser, 2001a; Volkmann et al., 2010). Expression of the multi-cistronic constructs in this transgenic Gal4 activator strain therefore allows the dynamics of the nucleus, the centrosome, and the emerging axon to be monitored simultaneously during THN migration in vivo. We demonstrate that the centrosome in migrating THN neurons is regularly overtaken by the nucleus and apparently does not lead migration by continuously advancing ahead of the nucleus. In addition, we reveal the temporal sequence of subcellular dynamics during THN neuron axonogenesis, which exclude an in vivo function of the centrosome in determining the site of axon outgrowth based on proximity to the centrosome. Thus, multicolor in vivo time-lapse imaging at subcellular resolution provides important insights into the dynamics of cellular processes and promises that the large fields of developmental genetics and cell biology can be merged in transparent zebrafish embryos into a field of vertebrate in vivo cell biology.

Results

Simultaneous subcellular intravital labeling in zebrafish cells

To fluorescently label subcellular structures in zebrafish, we first tested available fusion proteins in zebrafish Pac2 fibroblasts (Senghaas and Köster, 2009). Although β3-tubulin–GFP (mouse) was mostly localized to the cytoplasm (Fig. 1 A), GFP-tubulin (Fig. 1 B, mouse) and EB1-GFP (Fig. 1 C, mouse) each marked the microtubule network, although the specificity of labeling was dose dependent. In contrast, expression of GFP-DCX (Fig. 1 D, mouse) or Tau-GFP (Fig. 1 E, mouse) resulted in robust microtubule labeling, while EB3-GFP (Fig. 1 F, mouse) successfully marked microtubule plus-ends. These data indicate that subcellular labeling constructs cannot be easily transferred from one species to another, but require careful testing.

Subsequently, we used a similar approach to achieve mitochondrial targeting in zebrafish fibroblasts (mitochondrial targeting sequence from subunit VIII of human cytochrome c oxidase; Fig. 1 G), as well as labeling of the endoplasmatic reticulum (ER targeting sequence from calreticulin and ER retention sequence KDEL), the Golgi apparatus (N-terminal 81 aa of human β1-4 galactosyltransferase; Fig. 1 H), and the actin cytoskeleton (zebrafish cytoskeletal actin; Fig. 1 I). Finally, fluorescent protein fusions of the C terminus (Fig. 1 J) and the N terminus (Fig. 1 K) of a partial zebrafish centrin-2 cDNA were each used successfully to visualize the two centrioles of the centrosome at the hub of the microtubule network (Fig. 1 L, inset). To eventually allow

The inset shows a higher magnification of the centrosome at the hub of the microtubule network. These data present a collection of subcellular-targeted fluorescent proteins tested for their specificity in zebrafish cells. “mem” represents a membrane localization signal, which consists of a plamitylation and myristinylation sequence of the human Lck kinase.
Figure 2. Janus and Medusa Gal4 effector constructs for simultaneous expression of multiple subcellular labels. (A) Schematic representation of bidirectional Janus vectors J1 and J2. Upon binding of Gal4, two subcellular markers are expressed simultaneously (J1: H2B-mRFP labels the nucleus in red and GFP-DCX the microtubules in green; J2: memmRFP labels the membrane in red and H2B-CFP the nucleus in blue). (B) Schematic representation of Medusa vectors M1, M2, and M3. From each vector, the expression of three subcellular markers is activated in the presence of Gal4. M1 encodes H2B-CFP to label the nucleus in blue, memmRFP to mark the membrane in red, and Centrin2-YFP to label the centrioles of the centrosome in yellow. M2: H2B-mRFP to label the nucleus in red, GFP-DCX to label microtubules in green, and memCFP to label the membrane in blue. M3 codes for the same nuclear and membrane markers as M2, but contains EB3-GFP to label the plus-ends of microtubules. These data demonstrate that reliable coexpression of various transgenes can be achieved from Gal4-mediated multicistronic expression vectors. Images were obtained from living zebrafish embryos (24 hpf) coinjected at the one-cell stage with the respective Janus or Medusa vectors and a vector coding for Gal4. "mem" represents a membrane localization signal, which consists of a palmitoylation and myristinylation sequence of the human Lck kinase. Arrows in M1 indicate YFP-labeled centrosomes.
for multiple combinations of subcellular markers, we generated fusion proteins with spectrally different fluorescent proteins for most of these subcellular markers (Table S1).

Simultaneous multicolor labeling
To mediate the simultaneous expression of two fluorescent subcellular markers by Gal4 transcriptional activators, we generated bidirectional Gal4-dependent effector constructs. These so-called Janus vectors carry a series of Gal4 binding sites (upstream activating sequences, UAS) flanked on both sides by E1b minimal promoters (Fig. 2 A; Paquet et al., 2009).

Two of these Janus vectors (Fig. 2 A; J1, J2) were used to evaluate the degree of coexpression of the two markers in vitro by cotransfection with a KalTA4-encoding expression vector (pCS-KalTA4GI) into Pac2 fibroblasts (not depicted) and in vivo by coinjection with pCS-KalTA4GI at the one-cell stage. Coexpression was found to be reliable, both in Pac2 cells and in embryos (ranging from 97–99%), indicating that bound KalTA4 is able to activate gene expression upstream and downstream, even when only a single UAS site is used (Fig. S1). Currently though, we cannot distinguish whether bidirectional activation occurs after KalTA4 is bound to UAS or whether bidirectional activation requires off and on events of KalTA4 binding to UAS.

To further evaluate if the position upstream or downstream of the UAS sites is favored by KalTA4 for activating transgene expression, we generated the Janus constructs mRFP:5xUAS:GFP and GFP:5xUAS:mRFP. Both vectors were cotransfected with pCS-KalTA4GI into zebrafish Pac2 fibroblasts and protein levels of GFP and mRFP were determined by Western blot analysis (n = 3). When the ratios of the expression levels were compared for both orientations, the position downstream of the UAS was found to be slightly more strongly activated (~1.15 fold) than the position upstream of the UAS sites (unpublished data).

Although this differential activation does not represent a marked difference, this information may be valuable when the dose of the expressed transgenes is of importance.

Next, we established so-called Medusa vectors containing additional UAS sites or Janus units for triple or quadruple transgene expression. This, for example, allows the nucleus, the cytoplasmic membrane, and the centrosome (M1) to be labeled simultaneously from a single Medusa expression construct. In addition, Medusa vectors labeling microtubule fibers (M2) or microtubule plus-ends (M3) together with the nucleus and the cell membrane were successfully expressed in zebrafish embryos (Fig. 2 B) and allow one to clearly observe microtubule dynamics in nondividing (Video 1) or dividing cells (Videos 2 and 3) in living zebrafish embryos. Furthermore, two Janus cassettes can be combined to achieve quadruple subcellular labeling (not depicted).

Generation of a rhombic lip-specific KalTA4 activator line
To express transgenes specifically in cells derived from the rhombic lip, we identified regulatory elements of the zebrafish atonal1a homologue and flanked a KalTA4 expression cassette
cells have recently been identified as neurons of tegmental hindbrain nuclei (Volkmann et al., 2010). Intriguingly, as has been described before (Köster and Fraser, 2001a), these THN neurons already begin to project axons along the MHB and into the midbrain before and during ventral migration (Fig. 4 F, white arrow; see Video 4).

Subcellular analysis of THN neuronal progenitors during cell division

The establishment of subcellular markers and multi-cassette UAS-based vectors, in addition to the URL-specific KalTA4 expression in the transgenic strain Tg(atoh1a:Gal4TA4)hzm2, set up the possibility of doing in vivo cell biological experiments in a defined neuronal population. Tg(atoh1a:Gal4TA4)hzm2 embryos injected at the one-cell stage with the Medusa M1 construct showed expression of the subcellular markers in THN neuronal progenitors from at least 22 hpf onwards. THN neuronal progenitors were observed to span the entire cerebellar primordium, being connected by endfeet-like processes to the apically positioned URL and basally located MHB (Fig. 5 A). THN neuronal progenitors underwent interkinetic nuclear movements (INM) and divided strictly at or close to the apical side, along the ventricle

(KalTA4GipA; Distel et al., 2009) with them. Subsequently, transgenic fish Tg(atoh1a:Gal4TA4)hzm2 were generated using I-SceI-meganuclease mRNA coinjection (Babaryka et al., 2009). When crossed to Tg(4xUAS:GFP)hzm3 carriers, the offspring showed the expected pattern of GFP expression throughout the rhombic lip (Fig. 3, B and C). Although some ectopic GFP expression domains in the retina and optic tectum (Fig. 3 C) could be observed, GFP fluorescence throughout the hindbrain and in sensory hair cells recapitulated the expression of endogenous atonal1a, as confirmed by coexpression analysis against atonal1a mRNA (Fig. 3, A and D) and anti-GFP immunohistochemistry (Fig. 3, B, E, and F).

Confocal time-lapse recording of fluorescent URL-derived cells in embryos from crosses of Tg(atoh1a:Gal4TA4)hzm2 x Tg(shhb:Gal4TA4,5xUAS:mRFP)hzm2 (TG5xR; Distel et al., 2009), in which Gal4-expressing cells mosaically expressed mRFP, revealed that these cells divided at the URL starting at ~24 hours postfertilization (hpf; Fig. 4 C), and subsequently moved radially to the MHB while still connected to the URL by a long trailing process (Fig. 4 D). They eventually retracted this trailing process and migrated ventrally in a tangential manner along the MHB (Fig. 4, E and F). These early URL-emigrating cells have recently been identified as neurons of tegmental hindbrain nuclei (Volkmann et al., 2010). Intriguingly, as has been described before (Köster and Fraser, 2001a), these THN neurons already begin to project axons along the MHB and into the midbrain before and during ventral migration (Fig. 4 F, white arrow; see Video 4).
Coordination of centrosome dynamics during neuronal migration
• Distel et al.

As THN progenitors approach the MHB in preparation for ventral migration, however, the cells become more ventrally oriented, deviating now $\sim 65$ degrees from the apico-basal axis of the cerebellum (Fig. 6 F; Fig. S3; $66.9 \pm 6.9$, $n = 4$ cells). Medusa vector labeling of the centrosome, the membrane, and the nucleus revealed that THN progenitors initiating migration leave behind a long trailing process that remained connected with the apical membrane. The centrosome remained stationary in the apical process, near the ventricular surface (Fig. 6, B and C), until shortly before the apical process began to detach from the germinal zone. If neuronal migration is considered to be an event whereby a neuron follows a leading process and moves from its birth place to its terminal site of later function without being connected to either position, then the final forward movement of bipolar THN progenitors toward the MHB does not represent neuronal migration. Rather, the apically positioned centrosome within a trailing process still in contact with the germinal zone is characteristic of proliferating neural progenitors and argues that the nuclear translocation toward the MHB in conjunction with a ventral turn of the cell actually represents an extended final step of INM.

THN neuronal progenitors maintain a mitotic organization during preparation for migration

When time-lapse recordings were performed over a prolonged period of time, we observed that THN progenitors appeared to change their behavior. THN progenitors are elongated and during INM the long axis of cells in the mid-cerebellum is oriented only $\sim 32$ degrees off the apico-basal axis between the URL and MHB (Fig. 6, A–C; Fig. S3; $32.5 \pm 4.6$, $n = 5$ cells). As THN progenitors approach the MHB in preparation for ventral migration, however, the cells become more ventrally oriented, deviating now $\sim 65$ degrees from the apico-basal axis of the cerebellum (Fig. 6 F; Fig. S3; $66.9 \pm 6.9$, $n = 4$ cells). Medusa vector labeling of the centrosome, the membrane, and the nucleus revealed that THN progenitors initiating migration leave behind a long trailing process that remained connected with the apical membrane. The centrosome remained stationary in the apical process, near the ventricular surface (Fig. 6, B and C), until shortly before the apical process began to detach from the germinal zone. If neuronal migration is considered to be an event whereby a neuron follows a leading process and moves from its birth place to its terminal site of later function without being connected to either position, then the final forward movement of bipolar THN progenitors toward the MHB does not represent neuronal migration. Rather, the apically positioned centrosome within a trailing process still in contact with the germinal zone is characteristic of proliferating neural progenitors and argues that the nuclear translocation toward the MHB in conjunction with a ventral turn of the cell actually represents an extended final step of INM.
a similar average pace of nucleokinesis could be determined for gradual (0.22 µm/min) and saltatory (0.21 µm/min) nucleokinesis. During the latter though, the nucleus only moved on average 1.17 µm (±0.7 µm) during resting phases, while suddenly progressing 7.54 µm (±1.43 µm) during saltatory steps (n = 8 saltatory steps, 3 independent videos), which is more than a nuclear diameter (6.63 ± 0.67 µm, 10 nuclei measured). Thus, migration of THN neurons disconnected from the URL is marked by a switch from gradual to saltatory nucleokinesis.

The nucleus repeatedly surpasses the centrosome during nucleokinesis of THN neurons

A current model of saltatory nucleokinesis proposes that the centrosome permanently advances ahead of the nucleus, and that this organization is crucial for forward nuclear movement (Tsai and Gleeson, 2005; Métin et al., 2008). Indeed, during THN migration along the MHB, Medusa labeling revealed that a similar average pace of nucleokinesis could be determined for gradual (0.22 µm/min) and saltatory (0.21 µm/min) nucleokinesis. During the latter though, the nucleus only moved on average 1.17 µm (±0.7 µm) during resting phases, while suddenly progressing 7.54 µm (±1.43 µm) during saltatory steps (n = 8 saltatory steps, 3 independent videos), which is more than a nuclear diameter (6.63 ± 0.67 µm, 10 nuclei measured). Thus, migration of THN neurons disconnected from the URL is marked by a switch from gradual to saltatory nucleokinesis.
the centrosome moved ahead of the nucleus (Fig. 6, F and G, red arrow; G–I, yellow arrowhead). Intriguingly, our time-lapse recordings showed that the centrosome did not remain strictly in front of the nucleus. Instead, with each forward migratory step, the nucleus passes the centrosome (Fig. 7, C–F; Fig. 8 B, white asterisks). Plotting of distance over time showed that the centrosome moved at a nearly constant pace, whereas the nucleus alternated between resting and sudden advances (Fig. 8 D). Quantification revealed that the centrosome most often trailed the nucleus and is ahead of it for only ~35% of the time (Fig. 8 E). However, the centrosome repeatedly passed the nucleus during the preparatory phase of nuclear movement (Fig. 7, A–C, D, and E), when the centrosome seemed to indicate the direction of the next forward migratory step (n = 16 cells, 6 embryos; Video 8).

Thus, when the nucleus is not stationary (72.22% ± 14.40% of time), the centrosome and the nucleus move in the same direction (70.9% ± 9.9) and rarely opposite (8.4% ± 4.5%) to one another (n = 4 ventrally migrating cells, 3 embryos), indicating the same directionality of their movements (for a detailed analysis of the direction of movements of the centrosome and the nuclear centroid in the ventrally migrating cell shown in Fig. 8 B, see Fig. 8 F).

This iterative change in relative position of the nucleus and the centrosome to one another and the mostly trailing centrosome differ from the commonly used saltatory nucleokinetic model of a permanently leading centrosome during all steps of neuronal migration. Thus, either zebrafish THN neurons follow a different, cell population–specific form of saltatory nucleokinetic migration or saltatory nucleokinesis is less strictly orchestrated than previously thought, perhaps requiring a forward position of the centrosome only during a certain time window just before nuclear movement.

**Axonogenesis of THN neurons occurs at the MHB**

THN neurons approaching the MHB begin to extend from their leading edge a longer axon-like cellular process (Fig. 9 A, white asterisk; for axon projection into the midbrain see also final image sequence of Video 4). To verify the axonal identity of these emerging lead process structures, we performed immunohistochemistry against the axonal-specific marker acetylated α-tubulin. Acetylation of lysine40 of the α-tubulin subunit to stabilize microtubules is a key characteristic of the proximal axon and is important for axon outgrowth (Hammond et al., 2008; Witte and Bradke, 2008; Conde and Cáceres, 2009). Double-transgenic Tg(atoh1a:Gal4TA4)^kat2 × Tg(4xUAS:GFP)^kat3 embryos were raised until 40–42 hpf, by which time many GFP-expressing THN neurons had reached the MHB (Fig. 9 B). Subsequent fluorescent immunohistochemistry against GFP and acetylated α-tubulin.
that axonogenesis in THN neurons occurs in parallel to, or shortly after, proliferative INM is terminated.

Axonogenesis in THN neurons is not induced by proximity to the centrosome

Our subcellular in vivo time-lapse studies of centrosome dynamics, together with the immunohistochemical analysis of axon formation, argue that axonogenesis in zebrafish THN neurons is initiated by a membrane protrusion far away from the microtubule-organizing centrosome. To directly resolve the temporal sequence of axonogenesis and centrosome dynamics in THN neurons in vivo, we made use of the reporter Kif5C-YFP, which accumulates selectively in the forming axon very soon after axon
Coordination of centrosome dynamics during neuronal migration

Distel et al.

**Figure 9. THN progenitors initiate axonogenesis from their leading process independent of centrosome proximity.** (A) Lateral view of the cerebellar anlage of an ∼42-hpf Tg(atoh1a:Gal4TA4)UAS transgenic zebrafish embryo injected with Medusa vector M1. An axon-like protrusion (white asterisk) has formed at the time when the centrosome (white arrow) is still homing toward the soma. (B) Lateral view of a Tg(atoh1a:Gal4TA4)UAS x Tg(UAS:GFP)embryonic transgenic zebrafish embryo at 42 hpf. GFP-expressing cells are visualized by anti-GFP immunostaining (green) and acetylated microtubules by anti-acetylated tubulin immunostaining (red). (C) Enlargement of boxed area in B. Arrows indicate acetylated microtubules present in GFP-expressing THN progenitors, indicating the presence of axons by 42 hpf. (D–F) Lateral view of the cerebellum of a 40-hpf Tg(atoh1a:Gal4TA4)UAS x Tg(UAS:GFP) embryo injected with Medusa vector M1. (D) A THN progenitor (white asterisk) extends a process, the presumptive axon with a growth cone-like structure (red arrow), while the centrosome (white arrow) starts to translocate toward the soma. (E and F) The axon-like process elongates while the centrosome is moving toward the soma and is still far removed from the site of axonogenesis. These findings suggest that the site of axon formation in THN neurons is independent of a proximally positioned centrosome. Images in D–F are taken from Video 9. MHB, midbrain–hindbrain boundary; URL, upper rhombic lip.

specification (Jacobson et al., 2006; Reed et al., 2006). The Kif5C<sup>560</sup>-YFP axon reporter was expressed under UAS control in Tg(atoh1a:Gal4TA4)<sup>Gom2</sup> embryos together with the Janus construct J8, demarcating the nucleus by blue and the centrosome by red fluorescence (see Table S1). Therefore, the emergence of THN axons could be visualized in real time relative to the position and movement of the centrosome within the same THN neuron. We purposely chose a coexpression strategy of two different vectors for this experiment, rather than generating a triple-cistron Medusa construct, in order to yield a high degree of mosaicism of transgene expression, allowing for observation of Kif5C<sup>560</sup>-YFP localization in a single cell of a Janus-labeled group or cluster of THN neurons. We confirmed by immunohistochemistry that such single Kif5C<sup>560</sup>-YFP–positive processes coexpressed axon-specific acetylated tubulin (unpublished data).

Time-lapse sequences starting at 36 hpf were recorded from THN neurons that had reached the MHB, but showed a fluctuating cytoplasmic distribution of Kif5C<sup>560</sup>-YFP (Fig. 10 A, green arrow) and had their centrosomes (Fig. 10 A, red arrows) still positioned in the apical URL, indicating that these THN neurons had not yet initiated axonogenesis. Strikingly, Kif5C<sup>560</sup>-YFP fluorescence soon accumulated in front of the nucleus and close to the MHB (Fig. 10, B and C; green arrow), while the centrosome remained stationary in the URL and far away from the emerging axon (Fig. 10 B, red arrows). Only when axogenesis was well under way and the outgrowing axon extended ventrally along the MHB did the centrosome begin to detach from the proliferation zone and move toward the nucleus (Fig. 10, D–F; see also Video 10). This temporal sequence of axogenesis occurring significantly before centrosome movements toward the cell soma and leading edge demonstrates that in vivo proximity to the centrosome is not relevant for axon determination from the leading process of THN neurons. Interestingly, reorientation of the THN neuron from an apico-basal to a dorso-ventral orientation
Distel et al., 2009) that could be used for cell type–specific cell biological analysis. The presented collection of subcellular fluorescent reporters and their cassette-like assembly in Janus or Medusa vectors will facilitate Gal4-mediated in vivo cell biology in zebrafish, but also in other vertebrates such as chick embryos (Fig. S4). It has to be noted though, that obtaining high contrast for specific subcellular structures sometimes requires the careful adjustment of the expression levels. For example, strong expression levels for centrosome labeling will lead to saturation effects, with excess fluorescent protein accumulating in the cytoplasm. Low expression levels instead will only sparsely label the centrosome, making it too dim for fast image acquisition. The Gal4 system allows one to fine-tune expression levels by either adjusting the number of UAS sites or by selecting a

Discussion

In this study, we have expanded the use of Gal4 combinatorial genetics in zebrafish for cell biological characterization by establishing simultaneous expression of multiple subcellular markers in a cell type–specific manner. Enhancer and gene trap screens have already generated a multitude of zebrafish Gal4 activator strains (Davison et al., 2007; Scott et al., 2007; Asakawa et al., 2008; Distel et al., 2009) that could be used for cell type–specific cell biological analysis. The presented collection of subcellular fluorescent reporters and their cassette-like assembly in Janus or Medusa vectors will facilitate Gal4-mediated in vivo cell biology in zebrafish, but also in other vertebrates such as chick embryos (Fig. S4). It has to be noted though, that obtaining high contrast for specific subcellular structures sometimes requires the careful adjustment of the expression levels. For example, strong expression levels for centrosome labeling will lead to saturation effects, with excess fluorescent protein accumulating in the cytoplasm. Low expression levels instead will only sparsely label the centrosome, making it too dim for fast image acquisition. The Gal4 system allows one to fine-tune expression levels by either adjusting the number of UAS sites or by selecting a

Figure 10. In vivo imaging of axonogenesis. Lateral view of the cerebellar anlage of a 36-hpf Tg(atoh1a:Gal4TA4)hzm2 transgenic zebrafish embryo coinjected with Janus vector J8 (marking nucleus in blue and centrosome in red, red arrows) and 5xUAS:Kif5c-YFP (emerging axons labeled with yellow fluorescence, here shown in green). (A) Due to coinjection of two vectors, only the more anteriorly located cell expresses the Kif5c-YFP fusion protein. Kif5c-YFP is initially distributed throughout the soma of the cell (green arrow), while the centrosomes of both cells are localized at the apical side (red arrows). (B–D) Kif5c-YFP localizes to a protrusion, the later axon, in the front of the cell, at the time when the centrosome is homing toward the soma. (E and F) Kif5c-YFP localizes to a growth cone–like structure of the emerging axon, while the centrosome has not reached the soma. This temporal sequence of axonogenesis and centrosome dynamics reveals that a proximal position of the centrosome is not required for selecting the site of axon formation in THN neurons in vivo.

Images are taken from Video 10. MHB, midbrain-hindbrain boundary; URL, upper rhombic lip.

(compare position of nuclei in Fig. 10, C and F) also preceded the arrival of the centrosome in the cell soma (Fig. 10, C–F). This strongly suggests that repolarization during turning behavior of THN neurons is similarly not mediated by repositioning of the centrosome.
Gal4 activator with the appropriate transactivation potential (Distel et al., 2009). By this means, optimal labeling results can be achieved.

Medusa labeling showed that once THN neurons have become postmitotic, expressing markers such as PSA-NCAM or acetylated tubulin, and have initiated axonogenesis (Rieger et al., 2008), the apical centrosome-containing process detaches from the germinal URL and moves together with the centrosome toward the MHB-positioned cell somata to initiate neuronal migration. In a common model for tangentially migrating neurons, the centrosome typically moves significantly ahead of the nucleus, establishes an axonal swelling, and organizes the microtubule skeleton. This is followed by the saltatory translocation of the nucleus toward the displaced centrosome (Bellion et al., 2005; Schaar and McConnell, 2005; Ménin et al., 2008). Also in zebrafish, tangentially migrating facial branchiomotor neurons display such a leading centrosome, which reorients during migratory turns. Failure to maintain the proper apico-basal positioning of the centrosome is accompanied by migration in ectopic directions, suggesting a role for the centrosome in regulating directional migration (Grant and Moens, 2010). In this respect the ventral migration of THN neurons along the MHB displays an unexpected subcellular orchestration. Only during the preparation for nucleokinesis is the centrosome positioned ahead of the nucleus, being then overtaken during the saltatory forward translocation of the nucleus. For most of the time, the centrosome trailed the nucleus, although it moved at a constant pace even during resting periods of the nucleus. Thereby an iterative cycle of centrosome–nucleus leaptfrogging is created.

Interestingly, the role of the centrosome in permanently leading the nucleus of radially migrating neurons has also been called into question recently. In radially migrating cerebellar granule neurons, it was shown that the centrosome is similarly overtaken by the nucleus during nucleokinetic forward movements (Umeshima et al., 2007). In these neurons though, the centrosome advances ahead of the nucleus less regularly than in THN neurons and only during long resting phases. Notably, radial migration occurs along oriented glia fibers, which provide additional cues for the directionality of migration, whereas tangential migration of neurons occurs independently of a guiding glial meshwork. Therefore, tangential THN neuron migration may depend more strongly on a leading centrosome preparing forward migration during each migratory step, whereas radially migrating neurons may not need this consistent directional information from the centrosome. On the other hand, the centrosome in radially migrating cortical neurons does remain strictly ahead of the nucleus (Tsai et al., 2007). Taken together, these findings argue that, like in non-neuronal cells, the exact subcellular orchestration of saltatory nucleokinetic migration is strongly context dependent, varying with the neuronal cell type, local environment, and morphogenetic constraints.

A key role for the centrosome, and in particular its positioning, has been postulated for the induction of axonogenesis in several neuronal populations (Lefcort and Bentley, 1989; Zmuda and Rivas, 1998; Arimura and Kaibuchi, 2007). Findings in cultured hippocampal neurons and cortical neurons in vivo have established that the neurite nearest to the centrosome is selected to become the axon (de Anda et al., 2005, 2010). Subsequent axon extension though, does not require a functional centrosome (Stiess et al., 2010). Our in vivo time-lapse studies show that axonogenesis in THN neurons is initiated during the onset of migration and occurs clearly distant from the centrosome. These observations thus differ from hippocampal and cortical neurons, and THN neurons instead behave like retinal ganglion cells in the zebrafish retina, which initiate an axon from the basal process while retraction of the centrosome-containing apical process is still underway (Zolessi et al., 2006). Thus, in retinal ganglion cells and migratory THN neurons, the position of the centrosome does not predict the site of axonogenesis. Our findings argue that the cellular mechanisms of axonogenesis cannot be generalized and are, similar to migration, dependent on the cell type, morphogenetic constraints, and the makeup of the extra-cellular environment. For example, a strong influence on cerebellar granule neuron axonogenesis and centrosome positioning is exerted by the composition of the ECM and associated signaling molecules (Gupta et al., 2010), which can vary significantly among neuronal tissues. In THN neurons, cellular and molecular events occurring in the leading process itself may predispose the leading process to later axon formation. These events are probably initiated already during the extended interkinetic nuclear movement step of THN progenitors toward the MHB. Thus, the different molecular and cellular dynamics in the apical and leading processes, as well as their temporal orchestration, need to be further characterized in vivo in different cell types in order to better understand the course of neuronal development from birth to terminal differentiation. The cell type–specific multicolor labeling of individual neuronal cells, as established here, is a promising step in this direction.

**Materials and methods**

**Maintenance of fish**

Zebrafish strains were raised and maintained at 27°C in a manufactured fish facility (Aqua Schwarz GmbH, Göttingen, Germany) with circulating and constantly filtered water at 800–1,000 μS salinity (Kimmel et al., 1995; Westerfield, 1995). In the Tg(shhb:Gal4TA4,5xUAS:mRFP) strain (TgS5xr), the notchochord-specific shhb (formerly twhh) promoter element drives the expression of Gal4TA4, which in turn activates expression of the red fluorescent protein mRFP under control of five UAS sites and the Elb basal promoter (Babaryka et al., 2009; Distel et al., 2009).

**Construction of vectors**

S14: #801 pCS GFP-DCX. The ORF encoding GFP-DCX was isolated from the pEGFP-C2DCX vector [a kind gift of Fiona Francis, Institut Cochin, Université Paris Descartes, Paris, France] by Eco47III–SalI digest and cloned into StuI–SalI sites of pSK14xUASE1b vector (Köster and Fraser, 2001b). U15: #699 pSK14xUAS:H2B-mRFP. The ORF encoding H2B-mRFP was isolated from pCSH2B-mRFP [a kind gift of Sean Megason, Harvard Medical School, Boston, MA] by ApaI–SalI digest and cloned into StuI–SalI sites of pSK14xUASE1b vector (Köster and Fraser, 2001b). U16: #709 pSHh2B-mRFP:5xUAS:E1b. The E1b minimal promoter and the ORF encoding H2B-mRFP were isolated from pSHh2B-mRFP between XbaI and NotI and inserted into the SmaI site of the pSK5xUASE1b vector (Distel et al., 2009).

J1: #828 pSK-H2B-RFP:5xUAS:GFP-DCX. The ORF encoding GFP-DCX was isolated from pCSH2B-GFP-DCX vector [a kind gift of Juan Ramon Martinez de la Rosa, Institut Cochin, Paris, France] by XbaI–SalI digest and cloned into NotI–SalI sites of pSK5xUASE1b vector (Distel et al., 2009).

U17: #627 pSK14xUAS:H2B-GFP. H2B-GFP was isolated from pCSH2B-GFP vector (Klenow blunted)–ApaI digested and cloned into the XbaI site of pSK14xUASE1b vector (Köster and Fraser, 2001b).
of the Xhol (Klenow blunted)–Apal-digested pStk14xUASE1b vector (Küstner and Fraser, 2001b).

U18: #665 pSHK2B-GFP:5xUAS:EB3-GFP. The E1b minimal promoter and the ORF encoding H2B-GFP were isolated from U17 by Xbal–NotI (Klenow blunted) digested and inserted into the Smal site of the pSk5xUASE1b vector (Distel et al., 2009).

J1: #700 pSHK12B-GFP:5xUAS:mmemRFP. The ORF encoding mmemRFP was isolated from pSmemmRFP (a kind gift of Sean Megason) by Xhol (Klenow blunted)–Apal digest and inserted into EcoRV–Apal-digested U18. “mem” represents a membrane localization signal, which consists of a palmitoylation and myristinylation sequence of the human Lck kinase.

U2: #860 memmRFP:5xUAS. The E1b minimal promoter and the ORF encoding memmRFP were isolated from J1 by Xbal–NotI (Klenow blunted) digested and inserted into the Smal site of the pSk5xUASE1b vector (Distel et al., 2009). “mem” represents a membrane localization signal, which consists of a palmitoylation and myristinylation sequence of the human Lck kinase.

# 878 pH2B-CFP. The ORF encoding H2B was isolated from pH2B-CFP by NotI/Klenow blunted–XhoI and cloned into XbaI (Klenow blunted) digested pCS2+.

J2: #939 pSHKmemmRFP:5xUAS:H2B-CFP. The ORF encoding H2B-CFP was isolated from J2 by XhoI–Klenow blunted digested and inserted into Asp718-digested (Klenow blunted) U2.

J767 [pCR3.1-Centrin2]. The ORF of zebrafish centrin2 (acc. nr.: EU183505) was cloned by RT-PCR to generate C-terminal fusions using total RNA from adult brain and the following primers: HindIII centrin-up: 5′-TAACTGCTATGGGTCCGGCCTGTTAAGACATCAGTTGTTCTTCTC-3′. The fragment was subcloned into the pcRII-Topo vector (Invitrogen) and sequenced.

#769 [pCR3.1-Centrin2-5TOP]. The ORF of zebrafish centrin2 (acc. nr.: EU183505) was amplified by RT-PCR to generate N-terminal fusions using total RNA from adult brain and the following primers: BamH1 centrin-up: 5′-TTTCTAGATCATGACAGATGTCTTTTCT-3′ and centrin-low BamH1: 5′-TACGATAGCTCCCTGAAAGGTAGTTTGTTC-3′. The fragment was subcloned into the pcRII-Topo vector (Invitrogen) and sequenced.

#783 [pGFP-Centrin2]. The ORF encoding Centrin2 was isolated by BamH1–EcoRI digest from pCR3.1-Centrin2 and cloned into BamH1–EcoRI-digested pEGFP-C1 (Takara Bio Inc.).

S2: #848 pCSCentrin2-YFP. The ORF encoding Centrin2-YFP was isolated from pCSCentrin2-YFP by NotI (Klenow blunted)–XhoI and cloned into BglII–EcoRI-digested pCS2+ (Takara Bio Inc.).

U5: #996 pSK5xUAS:Cen2rin2-YFP. The ORF encoding Centrin2-YFP was isolated from pSCCentrin2-YFP by EcoRI–Apal digest and inserted into EcoRV–Apal-digested pStk5xUAS (Distel et al., 2009).

#1595 pSkmemmRFP:5xUAS:memCFP. The 5xUAS:YFP cassette was isolated from U5 by SpeI–Asp718 digest (Klenow blunted) and inserted into SpeI–Asp718-digested Centrin2-YFP (Klenow blunted). J2.

#938 pCenmRFP. mRFP of pCenmmRFP (a kind gift of Sean Megason) was removed by SnaBI–Apal digest and replaced with CFP from NotI (Klenow blunted)–Apal-digested pEGFP-C1 (Takara Bio Inc.). “mem” represents a membrane localization signal, which consists of a palmitoylation and myristinylation sequence of the human Lck kinase.

#997 pSh2B. The ORF encoding mmemRFP was isolated from S6 by Clal–Apal digest and inserted into Clal–Apal-digested pSk5xUAS.

M2: #998 pSHK12B-mRFP:5xUAS:GFP:DCX:5xUAS:mmemRFP. The 5xUAS:memCFP cassette was isolated from U6 by NotI (Klenow blunted) and inserted into Asp718-digested [Klenow blunted] J1.

S10: #771 pScb3-3GFP. The ORF encoding EB3-GFP was isolated from pEB3-GFP (a kind gift of Anna Akhmanova, Erasmus Medical Center, Rotterdam, The Netherlands) by NotI (Klenow blunted)–SalI-digested and inserted XbaI (Klenow blunted)–XhoI-digested pCS2+.

J4: #870 pSKH2B-mRFP:5xUAS:EB3-GFP. The ORF encoding EB3-GFP was isolated from S10 by Stul–Asp718 digest and inserted into EcoRV–Asp718-digested U16.

M3: #999 pSKH12B-mRFP:5xUAS:EB3-GFP:5xUAS:mmemRFP. The 5xUAS:memCFP cassette was isolated from U6 by NotI (Klenow blunted) and inserted into Asp718-digested [Klenow blunted] J4.

#868 pCstlTomato. The ORF encoding tdTomato was isolated from pSERTdTomato (a kind gift of Roger Tsien, University of California, San Diego, La Jolla, CA) by BamH1–EcoRI digest and inserted into BamH1–EcoRI-digested pCS2+.

S1: #879 pSCen2rin2-tdTomato. The ORF encoding Centrin2 was isolated from pCRII-Centrin2 by BamH1–HindIII digest and inserted into HindIII–HindIII-digested pCstlTomato.

#1532 pSK185xUAS:EB3-GFP. The E1b5xUAS:EB3-GFP cassette was isolated from U2 by EcoRI digest and inserted into EcoRI-digested pBSK.

U9: #2022 pSKH2B-CFP:5xUAS:EB3-GFP. The ORF encoding H2B-CFP was isolated from pCS2B-CFP by Asp718 digest and inserted into SmaI-digested pSK185xUAS:EB3-GFP.

J8: #2146 pSKH2B-CFP:5xUAS:Centrin2-tdTomato. The ORF encoding Centrin2-tdTomato was isolated from S1 by HindIII–Asp718 digest and inserted into HindIII–Asp718-digested pBSK.

pSC-Klf5c-YFP. Klf5c-YFP was PCR amplified from Klf5c-YFP (a kind gift of Gary Baker, Oregon Health and Science University, Portland, OR) and a Kozak sequence was added using primers Klf5cEcoHinforKo: 5′-AAGGAATCAGGTTACATTGATATGC-3′ and #399: 5′-GGGTCGACATGGGACTGCGCACTTCA-3′ and a Kozak sequence was added using primers Klf5cEcoHinforKo: 5′-AAGGAATCAGGTTACATTGATATGC-3′ and #399: 5′-GGGTCGACATGGGACTGCGCACTTCA-3′ and a Kozak sequence was added using primers Klf5cEcoHinforKo: 5′-AAGGAATCAGGTTACATTGATATGC-3′ and #399: 5′-GGGTCGACATGGGACTGCGCACTTCA-3′ and a Kozak sequence was added using primers Klf5cEcoHinforKo: 5′-AAGGAATCAGGTTACATTGATATGC-3′ and #399: 5′-GGGTCGACATGGGACTGCGCACTTCA-3′ (Köster et al., 2009). “mem” represents a membrane localization signal, which consists of a palmitoylation and myristinylation sequence of the human Lck kinase.

Further cloning strategies are available upon request.

Expression of atoh1a:KaTaI4G transgenic zebrafish

To express transgenes in rhombic lip–derived cells, KaTa4A was placed between upstream regulatory elements of the zebrafish atoh1a 1a promoter (hzm2-ATAGCGGCCGCTTCTGTTGGTTTGTGC-3′). The 5xUAS:YFP cassette was isolated from U5 by SpeI–Asp718 digest (Klenow blunted) and inserted into SpeI–Asp718-digested Centrin2-YFP (Klenow blunted). J2.

Microinjection

Zebrafish embryos were injected with expression plasmids (25 ng/μl each, 1.5 nl) at the one-cell stage. Raised embryos were screened for expression right before microscopy analysis.

Microscopy

For image recording, embryos were dechorionated and embedded in 1.2% ultra low melting agarose/30% Danieau (Distel and Köster, 2007). Images of living embryos and of transfected cells were recorded using a confocal microscope (LSM 510; Carl Zeiss, Inc.) and LSM software (Carl Zeiss, Inc.). Images of in situ hybridizations were recorded using an AxioPlan2 microscope equipped with an AxioCam HRc and Axiovision 4.5 software (all from Carl Zeiss, Inc.). Images in Fig. 1 and Fig. 2 B (M2, M3) were recorded using a 63x Plan-Apochromat oil immersion objective (NA 1.4); in Fig. 2, A and B (M1), Fig. 3, D–F, Figs. 5, 6, 7, 9, and 10 using a 40x C-Apochromat water immersion objective (NA 1.2) and in Fig. 3, A–C and Fig. 4 A using a 20x EC Plan-Neofluar objective (NA 0.5). Images in Figs. 4–7, Fig. 9, D–F, and Fig. 10 represent maximum intensity projections taken from respective videos of time-lapse analysis.

Quantification of subcellular dynamics

Migration angle analysis. In a lateral view of the cerebellum, the apico-basal axis was determined by drawing a horizontal line from the URL to the MBH, perpendicular to the MBH. The nuclear centroids of TH-N pinotrimmers
were tracked using the Manual Tracking tool of ImageJ software (NIH, Bethesda, MD). The angle between the migration path of the respective cell and the apico-basal axis of the cerebellum was determined in THN progenitors undergoing INM and neurons initiating ventral migration using Adobe Photoshop CS3.

Centrosome and nuclear centroid tracking. Centrosome and nuclear centroid tracking over time and measurements of migration distances and migration velocities of the respective organelles were performed on maximum projections of the respective z-stacks using the Manual Tracking tool of ImageJ software.

Generation of kymographs. The kymographs in Fig. 8, A and B were generated manually using Adobe Photoshop CS4. 2D maximum projections shown in Videos 6 and 8 were rotated 45 degrees counterclockwise and regions containing the nuclei (Video 6, Fig. 8 A) or containing the nucleus and the centrosome (Video 8, Fig. 8 B) were extracted for each time point. Cropped regions were assembled in one image starting with the earliest time point on the left.

Determination of the position of the centrosome with respect to the nuclear centroid and migration direction. A 0.4-µm-thick line was drawn through the nuclear centroid and orthogonal to the direction of cell migration, dividing the cell into two halves. The position of the centrosome was then scored manually to be either in the anterior half (anterior to the nuclear centroid), in the posterior half (posterior to the nuclear centroid), or on the line (scored as lateral to the nuclear centroid). Cells were analyzed during ventral migration, starting at the time point when the centrosome had reached the soma of the cell and ending when the cell no longer showed apparent migration. The pie chart in Fig. 8 was generated in Microsoft Excel.

Determination of directions of centrosomal and nuclear movements. To determine the direction of centrosomal and nuclear movements during ventral migration, images were rotated where necessary so that cells migrated approximately along the y axis. Afterward, the y position of the respective cell organelle was determined using ImageJ [Measure tool or Manual Tracking plugin]. Subsequent y positions were subtracted (and corrected for tissue growth if necessary) to yield the net movement. Movements less than 0.5 µm were scored as stationary. Greater movements were scored as in the direction of migration (forward) or as opposite to the direction of migration (backward).

The 3D bar graph of the respective movement combinations was generated in Microsoft Excel.

Transfection
Zebrafish Pac2 fibroblasts were maintained in Leibovitz L15 medium supplemented with 1x l-glutamine (Invitrogen) and 10% fetal bovine serum. Pac2 cells were transfected using the Effectene transfection kit (QIAGEN) or the Nanofectin transfection kit (PAA; Senghaas and Köster, 2009).

Immunohistochemistry
GFP-expressing offspring of g(2hlo)Ga4Gal4TAgm3m and tga4x(UAS: GFP) transgenic carriers (Distel et al., 2009) were fixed in 4% PFA at 36°C and 42 hpf for 12 h and transferred into 100% MeOH. Embryos were then incubated in H2O at room temperature for 1 h. Subsequently, embryos were washed with PBS/0.1% Tween (PTW) twice for 5 min each, after which embryos were incubated in 10 mM sodium citrate, pH 6.0/0.1% Tween for 15 min at 100°C for antigen retrieval. Subsequently, embryos were washed twice in PTW for 5 min each and blocked in 10% goat serum in PTW for 1 h at room temperature. Embryos were incubated with the primary antibodies chicken anti-GFP (1:500; Aves, catalog no. 1020) and mouse anti-acetylated tubulin (1:500; Sigma-Aldrich, catalog no. T6793) at 4°C overnight. After several washes in PTW, embryos were incubated with the secondary antibodies anti-mouse Alexa546 (1:100; Invitrogen) and anti–chicken FITC (1:100; Jackson Immunoresearch Laboratories, Inc., catalog no. 703 095 155) overnight at 4°C. Nuclei were stained using DAPI (1 µg/µl; Roche, catalog no. 10236276001).

Online supplemental material
Online supplemental material is provided with this manuscript, including a table of expression constructs and their identifier numbers, which should be used for construct ordering. In addition, figures showing expression (scored a Janus construct using a single UAS-site [Fig. S1], anti-PH3 immunohistochemistry for detecting proliferating cells in the developing cerebellum [Fig. S2]), a quantification of the ventral turning angle of migrating THN neurons [Fig. S3], and triple-cistronic Medusa vector expression in the developing chick tegumentum [Fig. S4] are provided. Finally, the supplemental material contains all of the videos and their respective legends referred to in this manuscript. Video 1 visualizes MT dynamics in a zebrafish keratinocyte. Videos 2 and 3 visualize MT dynamics in cells of a gastrulating zebrafish embryo. Video 4 shows a time-lapse recording of THN neuron migration. Video 5 shows nucleus and centrosome dynamics during interkinetic nuclear movements of THN progenitors, Videos 6 and 7 show trailing process retraction and centrosome dynamics in THN neurons preparing to migrate ventrally. Video 8 shows centrosome dynamics in a ventrally migrating THN neuron. Video 9 shows a time-lapse recording of an emerging axon of a THN neuron, and Video 10 shows the localization of the axon specific marker Kif5c-YFP and the centrosome during THN axonogenesis.

We are grateful for excellent fish husbandry and technical assistance by Petra Hammerl, Enrico Kühn, and Christine Lach. We thank Karsten Boldt for help with Western blot quantification and Damian Relfo for carefully reading and commenting on the manuscript. We thank Fiona Francis, Alexander Reugels, Jürgen Vehlen, Anna Akhranova, Sean Megason, Timm Schroeder, and Roger Tsien for generously providing us with different expression vectors.

Distel, M., J.C. Hocking, K. Vollmann, and R.W. Köster designed the experiments and performed the data analysis; M. Distel, J.C. Hocking, and K. Vollmann performed the experiments; M. Distel, J.C. Hocking, and R.W. Köster wrote the manuscript.

This work was generously supported by a BioFuture Award Grant of the German Ministry of Education and Research (BMBF 0311889), the German Research Association (DFG, KO1949/3-1), a Fellowship of the Studienstiftung des deutschen Volkes (M. Distel), and a postdoctoral fellowship from the Natural Sciences and Engineering Research Council (NSERC) of Canada (J.C. Hocking).
