Department of Biochemistry, University of Oxford, Oxford OX1 3QU, England, UK

Poly adenosine diphosphate (ADP)–ribosylation (PARylation) by poly ADP-ribose (PAR) polymerases (PARPs) is an early response to DNA double-strand breaks (DSBs). In this paper, we exploit Dicytostelium discoideum to uncover a novel role for PARylation in regulating nonhomologous end joining (NHEJ). PARylation occurred at single-strand breaks, and two PARPs, Adprt1b and Adprt2, were required for resistance to this kind of DNA damage. In contrast, although Adprt1b was dispensable for PARylation at DSBs, Adprt1a and, to a lesser extent, Adprt2 were required for this event. Disruption of adprt2 had a subtle impact on the ability of cells to perform NHEJ. However, disruption of adprt1a decreased the ability of cells to perform end joining with a concomitant increase in homologous recombination. PAR-dependent regulation of NHEJ was achieved through promoting recruitment and/or retention of Ku at DSBs. Furthermore, a PAR interaction motif in Ku70 was required for this regulation and efficient NHEJ. These data illustrate that PARylation at DSBs promotes NHEJ through recruitment or retention of repair factors at sites of DNA damage.

PARPs also become activated in response to DNA double-strand breaks (DSBs), which can be repaired by homologous recombination (HR) or nonhomologous end joining (NHEJ; Haber, 2000). Although PARP1 interacts with NHEJ proteins, including Ku and the DNA-dependent protein kinase catalytic subunit (Ariumi et al., 1999; Galande et al., 1999), classical NHEJ is normal in murine PARP1−/− cells (Yang et al., 2004). However, PARP1 is required to promote end joining by alternative NHEJ (A-NHEJ; Audebert et al., 2004; Robert et al., 2009) and has been implicated in HR to promote replication restart at damaged replication forks (Yang et al., 2004; Sugimura et al., 2008; Bryant et al., 2009).

Recently, we and others initiated a study of DNA repair in Dicytostelium discoideum and found it contains orthologues of NHEJ and other repair proteins absent in other invertebrates (Block and Lees-Miller, 2005; Hudson et al., 2005; Hsu et al., 2006; Zhang et al., 2009). This suggests that D. discoideum will prove a useful model to study certain repair pathways that show limited conservation in other genetically tractable organisms. In this regard, PARP activity is evident in D. discoideum, and
Consistent with activation of PARPs, PARylated proteins become evident after treatment with both agents (Fig. 1 A). Given that DNA damage-induced nuclear foci are a commonly used marker for posttranslational modifications at or adjacent to sites of DNA damage, we assessed SSB-induced PAR foci formation in *D. discoideum* nuclei after SSBs. Exposure of cells to H$_2$O$_2$ (Fig. 1 B) or MMS (Fig. 1 C and Fig. S1, A and B) induces PAR-positive nuclei in a dose- and time-dependent manner. PAR staining is pannuclear at high doses of H$_2$O$_2$, whereas a punctate staining pattern is evident at lower doses (Fig. 1 B). Robust induction of γ-H2AX foci is not apparent at the H$_2$O$_2$ and MMS concentrations used, indicating PARylation is not a consequence of secondary DSBs (Fig. S1, C and D). To illustrate staining is a consequence of PAR synthesis, cells were treated with PARP inhibitors. Benzamide has previously been shown to inhibit PARylation in *D. discoideum* (Rajawat et al., 2007), whereas NU1025 was used as a higher potency alternative. Pretreatment of cells with either agent inhibits PAR nuclear staining in response to H$_2$O$_2$ and MMS (Fig. 1, D and E).

Adprts have been isolated from this organism (Rickwood and Osman, 1979; Kofler et al., 1993). Here, we analyze the role of *D. discoideum* Adprts in DNA repair and find that, similar to other organisms, multiple Adprts are required for *D. discoideum* to tolerate SSBs. Furthermore, we exploit *D. discoideum* to uncover a third PARP that is required for DSBR repair and illustrate that PARylation promotes NHEJ through retention of repair factors at damage via a PAR interaction domain present in Ku70.

**Results and discussion**

**D. discoideum** Adprts are required for tolerance to SSBs

Given that vertebrate PARPs are required for SSB repair, we wished to establish whether Adprt enzymes perform a similar function in *D. discoideum*. To achieve this, we assessed whether PARylation is induced after SSBs in this organism. Cells were exposed to H$_2$O$_2$ or methanesulfonate (MMS), and PARylation was assessed by Western blotting using a PAR antibody.

Consistent with activation of PARPs, PARylated proteins become evident after treatment with both agents (Fig. 1 A).

Given that DNA damage-induced nuclear foci are a commonly used marker for posttranslational modifications at or adjacent to sites of DNA damage, we assessed SSB-induced PAR foci formation in *D. discoideum* nuclei after SSBs. Exposure of cells to H$_2$O$_2$ (Fig. 1 B) or MMS (Fig. 1 C and Fig. S1, A and B) induces PAR-positive nuclei in a dose- and time-dependent manner. PAR staining is pannuclear at high doses of H$_2$O$_2$, whereas a punctate staining pattern is evident at lower doses (Fig. 1 B). Robust induction of γ-H2AX foci is not apparent at the H$_2$O$_2$ and MMS concentrations used, indicating PARylation is not a consequence of secondary DSBs (Fig. S1, C and D). To illustrate staining is a consequence of PAR synthesis, cells were treated with PARP inhibitors. Benzamide has previously been shown to inhibit PARylation in *D. discoideum* (Rajawat et al., 2007), whereas NU1025 was used as a higher potency alternative. Pretreatment of cells with either agent inhibits PAR nuclear staining in response to H$_2$O$_2$ and MMS (Fig. 1, D and E).
these strains exhibit a significant defect in PARylation after exposure to 5 mM MMS for 30 min (Fig. 2 B) or shorter times (not depicted). SSB-induced PARylation in the adprt1a− strain is reflected in a lack of sensitivity of cells to MMS (Fig. 2 C). However, adprt1b− and adprt2− strains exhibit increased sensitivity to MMS and H2O2 compared with parental controls (Fig. 2 C and Fig. S1, F–I). The adprt1b− and adprt2− strains are not radiosensitive, arguing against sensitivity to MMS being a consequence of DSBs sustained at the doses of MMS used (Fig. S1 E). Collectively, these data support a role for Adprt1b and Adprt2 in cellular resistance to SSBs and indicate conservation of a PAR-dependent SSB repair pathway in D. discoideum.

Next, we assessed which Adprt enzymes are required for SSB repair. Vertebrate Adprts can be divided into five subgroups (Otto et al., 2005), with group 1 containing the DNA damage-responsive PARPs, PARP1 and PARP2, in addition to PARP3 and PARP4. D. discoideum contains 13 proteins with putative Adprt catalytic domains, including orthologues of PARPs 1–4 (dictyBase; Otto et al., 2005). Three of these proteins, Adprt1a, Adprt1b, and Adprt2, contain PARP catalytic domains that exhibit a significant homology to PARP1 (Fig. 2 A; Otto et al., 2005).

To test the role of Adprt enzymes in SSB repair, we generated strains disrupted in the adprt1a or adprt2 genes and obtained strains disrupted in adprt1b (Sawai et al., 2007). None of
activity (Fig. 3 B). PARylation remains intact in NU1025, illustrating this event is mediated through PARP staining (Fig. 3 A). DSB-induced PARylation is inhibited by doses of phleomycin, whereas lower doses result in punctate nuclei (Fig. 3 A). Pannuclear PAR staining is observed at high nuclear proteins, as judged by the appearance of PAR-positive the DSB-inducing agent phleomycin results in PARylation of

Figure 3. Adprt1a is required for PARylation after DSBs. (A) Ax2 cells were treated with phleomycin (micrograms per milliliter) and subjected to immunofluorescence using PAR antibodies. Data are representative of three independent experiments. Cells were categorized into those that exhibit pannuclear staining or PAR nuclear foci. (B) Ax2 cells were treated with 1 mM NU1025 or DMSO before exposure to 100 µg/ml phleomycin for 30 min. Cells were subjected to immunofluorescence using PAR antibodies. (C) The indicated strains and their respective parental controls, Ax2 and Ax4, were assessed for PARylation after phleomycin treatment as in B. The percentages of PAR-positive cells were scored from a population of >200 cells. Error bars represent the SEM from three independent experiments.

* P < 0.05 compared with the positive control (Ax2 + phleomycin).

Adprt1a is required to promote NHEJ

Having established a role for Adprt enzymes in SSB repair, we assessed their role in DSB repair. Treatment of Ax2 cells with the DSB-inducing agent phleomycin results in PARylation of nuclear proteins, as judged by the appearance of PAR-positive nuclei (Fig. 3 A). Pannuclear PAR staining is observed at high doses of phleomycin, whereas lower doses result in punctate staining (Fig. 3 A). DSB-induced PARylation is inhibited by NU1025, illustrating this event is mediated through PARP activity (Fig. 3 B). PARylation remains intact in adprt1b− cells after DSBs (Fig. 3 C). In contrast to SSBs, a modest reduction of DSB-induced PARylation is observed in adprt2− cells, whereas a significant reduction is evident in the adprt1a− strain (Fig. 3 C and Fig. S2 A). This reduction in PARylation is further decreased by disrupting adprt2 and adprt1a in combination (Fig. 3 C). These observations suggest that although Adprt1b and Adprt2 are required for tolerance to SSBs, Adprt1a and, to a lesser extent, Adprt2 are required for nuclear PARylation after DSBs.

Given the reduced ability of adprt1a− and adprt2− cells to PARylate nuclear proteins after DSBs, we assessed their ability to repair these DNA lesions. To assess NHEJ, we exploited the observation that transfection of linearized plasmid DNA along with the restriction enzyme used for linearization results in stimulation of DNA integration into the genome by restriction enzyme–mediated integration (REMI; Kuspa and Loomis, 1992). The ligation of the vector at endogenous restriction enzyme sites and the fact that vector DNA contains limited sequence homology to the D. discoideum genome suggest that REMI is mediated by NHEJ. Consistent with this, REMI is dependent on Ku70, Ku80, and other components of the NHEJ pathway (Fig. 4 A and Fig. 5 F; Hsu et al., 2011). The adprt1a− strain has a reduced REMI index comparable with ku80− cells, indicating a role for Adprt1a in promoting NHEJ (Fig. 4 A and Fig. S2 B). In contrast, adprt2− cells exhibit a modest reduction in the ability to perform REMI, whereas disruption of adprt2− and adprt1a− in combination does not further exacerbate the REMI defect of adprt1a− cells (Fig. 4 A). These data suggest that although Adprt2 may contribute toward promoting NHEJ, Adprt1a is the principle PARP required to regulate this pathway. In further support for a role of Adprt1a in NHEJ, adprt1a− cells are sensitive to DSBs administered during spor germination (Fig. 4 B and Fig. S2 C), a stage of the D. discoideum life cycle when cells are reliant on NHEJ to tolerate DSBs (Hudson et al., 2005).

Disruption of NHEJ promotes HR in several organisms (Pierce et al., 2001; Zhang et al., 2007; Barlow et al., 2008). Given the requirement for adprt1a in promoting NHEJ, we assessed the impact of disrupting this gene on the ability of cells to perform HR. Accordingly, we assessed targeted HR efficiency at the cdk8 locus in adprt1a− cells and found it to be elevated 4.5-fold compared with Ax2 (Fig. 4 C). Collectively, these data indicate that DSB-induced PARylation by Adprt1a promotes NHEJ at the expense of HR.

PARylation promotes NHEJ through retention of Ku at DSBs

Next, we assessed whether the inability to perform NHEJ in adprt1a− cells reflects a reduced capacity to recruit NHEJ factors to DNA lesions. Subcellular fractionation experiments reveal that NHEJ proteins become enriched in chromatin isolated from vertebrate cells after DSBs (Drouet et al., 2005). Using the same technique in D. discoideum, we observed enrichment of Ku80 in chromatin fractions after DSBs in Ax2 cells. DSB-induced enrichment of Ku80 in chromatin was reduced in adprt1a− cells compared with Ax2, illustrating that Adprt1a is required to recruit and/or retain Ku at DSBs (Fig. 5 A and Fig. S2, D and E).
PAR polymers act as recognition modules to recruit factors to DNA lesions through PAR interaction domains (Kleine and Lüscher, 2009). One such domain, the PAR-binding zinc finger (PBZ) motif, is required for CHFR to fulfill its role in the antephase checkpoint, implicating this motif in regulating the DDR (Ahel et al., 2008). The *D. discoideum* genome contains several proteins that exhibit a PBZ domain, including Ku70 (Fig. 5 B; Ahel et al., 2008). To determine whether the PBZ domain of *D. discoideum* Ku70 is capable of interacting with PAR, we expressed and purified the C-terminal 74 amino acids of Ku70 fused to GST (GST-Ku70C) or the same protein lacking the C-terminal 25 amino acids that spans the PBZ domain (GST-Ku70ΔPBZ) and tested their ability to bind PAR. Consistent with the PBZ domain of Ku70 being able to interact with PAR, GST-Ku70C, but not GST-Ku70ΔPBZ, is able to bind PAR in vitro (Fig. 5 C).

To assess a requirement for the PBZ domain of Ku70 in NHEJ, we generated a *ku70* strain and expressed full-length wild-type Myc-tagged Ku70 (Myc-Ku70) or Myc-Ku70 lacking the PBZ domain (Myc-Ku70ΔPBZ) in these cells (Fig. 5 D). Importantly, both proteins coimmunoprecipitate with Ku80, indicating they interact with their biologically relevant partner (Fig. 5 D). In Myc-Ku70–expressing cells, Ku80 becomes enriched in chromatin after DSBs (Fig. 5 E). Importantly, Myc-Ku70ΔPBZ–expressing cells exhibit reduced enrichment of Ku80 and Myc-Ku70ΔPBZ in chromatin after DSBs, presumably through an inability of Ku to be recruited and/or retained at DSBs (Fig. 5 E and Fig. S2 F). Although Myc-Ku70 rescues the NHEJ defect of *ku70* cells, Myc-Ku70ΔPBZ is unable to do so to the same degree (Fig. 5 F). Collectively, these data suggest the PBZ domain of Ku70 is required to promote NHEJ.

**Concluding remarks**

Our observations that disruption of *adprt1b* and *adprt2* sensitizes cells to agents that induce SSBs illustrate that the role of PARylation in SSB repair is largely conserved in *D. discoideum*. The involvement of two PARPs in SSB tolerance is reminiscent of the situation in mammals. PARP2 was initially discovered as a result of residual PARylation in PARP1-deficient mice after DNA damage (Amé et al., 1999). In addition, *parp2*/* parp2* mice are sensitive to DNA damage and exhibit increased chromosome instability after exposure to alkylating agents and a delay in repair of this variety of DNA damage (Schreiber et al., 2002; Ménissier de Murcia et al., 2003). Our data illustrating that both Adprt1b and Adprt2 respond to SSBs would support the role of multiple PARPs in this response and indicate conservation of a PAR-dependent SSB repair pathway in *D. discoideum*.

Importantly, we identify Adprt1a as a third PARP that functions in the DDR. Although Adprt1a is dispensable for cells to tolerate SSBs, it is required for NHEJ. We also observe a modest decrease in DSB-induced PARylation in *adprt2* cells. This is reflected in a subtle reduction of the REMI index of these cells. Collectively, these data imply that, similar to SSBs, multiple PARPs, namely Adprt1a and Adprt2, are involved in a PAR-dependent SSB repair pathway in *D. discoideum*.

Recently, PARP1 has been implicated in promoting end joining by the A-NHEJ pathway (Audebert et al., 2004; Robert et al., 2009). A possibility, therefore, is that Adprt1a may be involved in A-NHEJ. However, we use REMI of plasmid

---

**Figure 4. Adprt1a is required to promote NHEJ.** (A) REMI efficiency of the indicated strains was assessed as described in Materials and methods. The numbers analyzed were such that experimental strains were compared with >200 colonies from the positive control (Ax2 plus the restriction enzyme). Data are represented as the percentage of REMI induction relative to parental Ax2 controls. *, P < 0.05 compared with the positive control (Ax2). (B) Ax2, *adprt1a*, and *ku80* spores were germinated before exposure to phleomycin, and cell survival was established as described in Materials and methods. (C) Ax2 and *adprt1a* cells were assessed for HR efficiency by measuring targeted integration of the blasticidin resistance cassette at the *cdk8* locus. The percentage of HR is the proportion of aggregation-deficient colonies against the total number of blasticidin-resistant colonies. The n number represents to total of blasticidin-resistant colonies analyzed from multiple independent transfections. Error bars represent the SEM from three independent experiments.
Figure 5. The PBZ domain in *D. discoideum* Ku70 is required for NHEJ. (A) The indicated strains were exposed to phleomycin as indicated. After 80 min, the indicated cell fractions were analyzed by Western blotting. (B) Alignment of the PBZ domains present in *D. discoideum* (Dd) Ku70 and vertebrate APLF (APLF1 and APLF2), SNM1, and CHFR. Conserved amino acids are highlighted in black, and similar amino acids are represented in gray. (C) Serial dilutions of GST, GST fused to the C terminus of Ku70 (GST-Ku70C), or GST fused to the same fragment lacking the PBZ domain (GST-Ku70CΔPBZ) were blotted onto nitrocellulose filters. Inclines represent the relative amount of protein blotted onto the filter. After incubation in PAR polymer, Western blotting was performed using the indicated antibodies. (D, left) Whole-cell extracts were prepared from the indicated strains and subjected to Western blotting. The indicated strains were incubated with phleomycin, and Ku was immunoprecipitated (IP) from whole-cell extracts using Ku80 antisera. (right) Myc-Ku70 was confirmed by Western blotting (WB) using Myc antisera. (E) The indicated strains were left untreated or exposed to phleomycin. After 80 min, the indicated cellular fractions were analyzed by Western blotting. (F) REMI efficiency of the indicated strains was assessed as in Fig 4 A. The numbers analyzed were such that experimental strains were compared with >200 colonies from the positive control (ku70− cells expressing Myc-Ku70 plus restriction enzyme). The data are represented as the percentage of REMI induction relative to ku70− cells expressing Myc-Ku70. Error bars represent the SEM from three independent experiments. *, P < 0.05 compared with the positive control (ku70− cells expressing Myc-Ku70). Molecular masses are given in kilodaltons.
DNA into the genome of D. discoideum as an assay for NHEJ, which occurs accurately at endogenous restriction enzyme sites (Kuspa and Loomis, 1992) and is dependent on Ku70 and Ku80. A-NHEJ is Ku independent and involves extensive processing of DNA termini that will ablate restriction site integrity. We therefore favor that Adprt1a and Adprt2 are involved in classical NHEJ.

Our data suggest that DBS-induced PARylation promotes NHEJ by retention of repair factors at DSBs through the PBZ motif in Ku70. This conclusion is based on our observations that (a) DBS-induced PARylation and NHEJ are compromised in the adprt1a− strain, (b) enrichment of Ku on chromatin after DSBs is reduced in adprt1a− cells, and (c) recombinant Ku70 lacking the C-terminal PBZ domain exhibits a reduced ability to be enriched in chromatin after DSBs and to promote NHEJ compared with recombinant wild-type Ku70. Given the pivotal role of Ku in initiating NHEJ, we believe the NHEJ defect in adprt1a− or Myc-Ku70ΔPBZ–expressing cells suggests an inability to assemble and/or retain NHEJ factors at DSBs. This is reminiscent of the situation in SSB repair in which PAR polymers promote accumulation of repair proteins at DNA damage (El-Khamisy et al., 2003; Okano et al., 2003; Bekker-Jensen et al., 2007; Kanno et al., 2007; Rulten et al., 2008). Consistent with this hypothesis, human PARP3 has recently been implicated in facilitating NHEJ through promoting the accumulation of APLF and XRCC4–ligase IV at DSBs (Rulten et al., 2011).

Neither vertebrate Ku70 nor Ku80 possesses a PBZ domain. However, although the PBZ domain is evident in several D. discoideum DDR proteins, only three human proteins possess this motif (APLF, SNM1, and CHFR; Ahel et al., 2008). We have yet to identify APLF in D. discoideum. Although speculative, an interesting possibility is that the PBZ domain is evident in several D. discoideum proteins to compensate for the absence of APLF. A prediction of this model would be that APLF functions in a variety of DDR pathways, including NHEJ. In this regard, APLF has been implicated in SSB repair, and similar to our observations, its PBZ domain is required for accumulation of NHEJ factors at DSBs (Bekker-Jensen et al., 2007; Iles et al., 2007; Kanno et al., 2007; Rulten et al., 2008, 2011). We have yet to identify the proteins PARylated at DNA lesions in D. discoideum. However, given that PARylation of histones recruits repair factors to strand breaks in vertebrates (Rulten et al., 2011), it will be interesting to assess whether histones are similarly PARylated in response to DSBs in D. discoideum and act to retain Ku at sites of DNA damage.

Materials and methods

Sequence alignments
D. discoideum nucleic acid and predicted protein sequences were obtained from dicytBase, and other sequences were obtained from the National Center for Biotechnology Information. The MultiAlin interface was used for DNA sequence alignment (Corpet, 1988), and ClustalW was used to align protein sequences. Protein domains were identified using InterProScan.

Cell culture and strain generation
D. discoideum strains were grown using standard procedures, either axenically or on SM agar in association with Klebsiella aerogenes. An outline of the strategy to generate the strains used in this study and their verification is illustrated (Fig. S3). To generate the adprt1a disruption strain, DNA fragments upstream (nucleotides 1,070–1,907) and downstream (nucleotides 3,643–4,375) of the adprt1a catalytic domain (nucleotides 2,420–3,404) were generated by PCR from Ax2 genomic DNA. These fragments were cloned on either side of a blasticidin resistance cassette contained within the pLPB plasmid (Faix et al., 2004) using KpnI–HindIII and BamHI–NotI, respectively. A similar procedure was followed to disrupt the adprt2 gene by cloning upstream (nucleotides 543–1,500) and downstream (nucleotides 2,482–3,236) DNA fragments flanking the Adprt2 catalytic domain into pLPB PL using KpnI–HindIII and BamHI–NotI, respectively. A ku70− strain was generated by cloning upstream (nucleotides −880 to 217) and downstream (nucleotides 2,357–2,786) DNA fragments into pLPBPL using KpnI–HindIII and PstI–BamHI, respectively. This ku70− disruption construct targeted the entire ku70 gene for deletion. Cells were transfected with the disruption constructs and subjected to selection with 10 µg/ml blasticidin the following day. Blastidicin-resistant clones were isolated using standard procedures, and gene disruption was verified by PCR and Southern blotting. The adprt1b− strain was a gift from T. Cox (Princeton University, Princeton, NJ) and A. Kuspa (Baylor College of Medicine, Houston, TX).

Two independent clones of the adprt1a− and adprt2− strains were analyzed (adprt1a− w and adprt1a− z; adprt2− and adprt2− 2). Although only adprt1a− w and adprt2− are illustrated in the main figures on the manuscript, data from both clones are illustrated in Fig. S1 and Fig. S2. A ∆Xaa strain harboring a blasticidin resistance cassette was removed from the adprt1a− and ku70− strains as described previously (Faix et al., 2004). In brief, strains were transformed with the pDEX-NLScre plasmid, and transformants were transiently selected with 20 µg/ml G418 before being grown in media containing no antibiotics. Surviving colonies were screened for sensitivity to 10 µg/ml blasticidin and 20 µg/ml G418. Cells sensitive to both blasticidin and G418 were cloned on SM agar containing a K. aerogenes lawn, and clones were subjected to PCR to confirm the removal of the blasticidin resistance cassette.

The ku70− strain was complemented with either full-length Ku70 or Ku70 containing a 25-aa MscA C-terminal deletion that includes the PBZ domain contained within the pDXA-3C expression vector (Manstein et al., 1993). In both cases, the N-terminal Ku70 primer contained a KpnI restriction site and Myc tag, and the C-terminal primer contained an XbaI restriction site. Strains were transformed with the pDXA-3C complementation vectors and the pREP helper plasmid and subjected to selection with 10 µg/ml G418.

Immunoblotting and antibodies
Whole-cell extracts were prepared by washing cultures in KK2 before boiling cells in Laemmli buffer for 20 min (Hudson et al., 2005). Antibodies were obtained from the following sources: PAR (Trevigen), γH2AX (Abcam), Ku80 (Hudson et al., 2005), actin (Santa Cruz Biotechnology, Inc.), and Myc (Cell Signaling Technology).

Immunoprecipitation of Ku80
Exponentially growing cells were seeded at 5 × 10 6 cells/ml and treated with 100 µg/ml filipin for 30 min with rotation. Cells were washed twice in KK2, resuspended to a final density of 10 6 cells/ml in lysis buffer (50 mM Tris, pH 8.0, 200 mM NaCl, 1% Triton X-100, 1 mM EDTA, 50 U/ml benzamidine [EMD], 10 mM sodium butyrate, 1 mM NaF, 20 mM β-glycerophosphate, 1 mM sodium orthovanadate, 1 µM microcystin, and protease inhibitor cocktail [Roche]), and incubated with rotation for 30 min at 4°C. Cell lysates were centrifuged at 14,000 rpm for 10 min, and the supernatant was isolated and precleared with protein G-Sepharose beads at 4°C for 1 h before incubation with Ku80 serum (Hudson et al., 2005) for 30 min at 4°C, followed by an incubation with protein G-Sepharose beads for 45 min at 4°C, with rotation. The beads were pelleted at 500 rpm for 2 min and washed three times with lysis buffer before resuspending the beads in SDS loading buffer containing 100 mM DTT. Samples were analyzed by Western blotting (Hudson et al., 2005).

Protein expression and purification
A fragment of the ku70 gene that encodes the C terminus of Ku70 spanning amino acids 835–909 or the same fragment lacking the last 26 amino acids that encode the PBZ domain was inserted into the pGEX6P-1 vector (GE Healthcare) via BamHI and XhoI sites (termed GST-Ku70C and GST-Ku70CΔPBZ, respectively). GST-tagged proteins were expressed and purified according to the manufacturer’s instructions.
PAR-binding binding

Twofold serial dilutions of proteins ranging in concentration from 2.5 to 0.625 pmol were slot blotted onto a nitrocellulose membrane, which was subsequently blocked with 5% milk in TBST buffer (Tris-HCL, pH 7.5, 150 mM NaCl, and 0.05% Tween 20). After incubation with the PAR polyclonal (1:5,000 dilution) in TBST for 1 h, membranes were washed once with TBST followed by TBST containing 1 M NaCl. After a final wash in TBST, filters were incubated in anti-PAR or GST antibodies diluted in 5% milk in TBST buffer and incubated at 4°C overnight. Filters were washed three times in TBST before incubation with HRP-conjugated secondary antibody (Dako). After a final three washes in TBST, signals were detected with ECL Western blotting reagent.

Immunofluorescence analysis of DNA damage-induced staining

Cells were allowed to adhere to coverslips for 1 h before being incubated in media containing the indicated concentrations of phleomycin, MMS, or H2O2 for the times stated in the figure. Where indicated, coverslips were mock treated or preincubated for 1 h in media containing 1 mM NU1025 (Enzo Life Sciences) or 5 mM benzamide (Enzo Life Sciences) before addition of the DNA-damaging agent. Coverslips were incubated for 5 min in ice-cold nuclear extraction buffer (10 mM Pipes, pH 6.8, 300 mM sucrose, 3 mM MgCl2, 20 mM NaCl, and 0.5% Triton X-100) before being washed in TBS and fixed with 70% ethanol for a further 5 min. Coverslips were finally rinsed in 100% methanol and washed twice with TBS.

Coverslips were blocked for 1 h at room temperature in 10% swine serum before incubation in the relevant antibody for 1 h at room temperature. Coverslips were washed three times in TBS, incubated with TRITC-conjugated secondary antibody (Dako) for 1 h at room temperature, and washed three more times with TBS. Coverslips were mounted onto glass slides with VECTASHIELD mounting media containing DAPI (Vector Laboratories) and visualized with a microscope (IX71; Olympus) at a magnification of 100× with a lens (Olympus) and immersion oil (Lenoz). All microscopy was performed at room temperature. All images were acquired on a camera (C10600-10H; Hamamatsu Photonics) using HCImage Acquisition (Hamamatsu Photonics) image software and processed in Photoshop (Adobe).

Sensitivity assays

Exponentially growing D. discoideum were seeded at a density of 106 cells/ml. Phleomycin (Sigma-Aldrich), MMS (Sigma-Aldrich), or H2O2 (Sigma-Aldrich) was added at the concentrations indicated in the figure, and cells were incubated at 22°C while being shaken at 100 rpm. After 1 h, cells were diluted to 104 cells/ml in KK2, and 250 cells were plated onto duplicate 140-mm Petri dishes containing K. aerogenes in association with SM agar. Petri dishes were incubated in the dark at 22°C, and survival was assessed by counting the number of colonies visible 3, 4, and 5 d after plating. Sensitivity assays using germinated spores were performed as described previously (Hudson et al., 2005). In brief, exponentially growing cells were seeded at 5 × 107 cells/ml and exposed to phleomycin or H2O2. At the time points indicated in the figure, cells were washed in KK2 buffer and resuspended in nuclear lysis buffer (50 mM Hepes, pH 7.5, 150 mM NaCl, 1 mM EDTA, 1 mM microcystin, 1 mM NaF, 2 mM sodium orthovanadate, and protease inhibitor cocktail) supplemented with 0.1% Triton X-100 to a final density of 3 × 107 cells/ml. Cells were incubated for 15 min at 4°C and then centrifuged at 14,000 g for 5 min, giving rise to a pellet and supernatant fraction S1. The pellet was resuspended in nuclear lysis + 0.1% Triton X-100 for a further 15 min at 4°C and centrifuged at 14,000 g for 5 min. The supernatant was pooled with the S1 fraction, and the pellet was resuspended in nuclear lysis buffer + 200 µg/ml RNase A (Sigma-Aldrich), incubated with rotation at room temperature for 30 min, and repelleted as before to give fraction P2. The P2 pellet was resuspended in SDS loading buffer containing 100 mM DTT. Fractions were analyzed by Western blotting using the antibodies indicated in the figure.

Online supplemental material

Fig. S1 further shows that PARylation is stimulated after SSBs and that Adprt1b and Adprt2 are required to tolerate this variety of DNA damage. Fig. S2 further illustrates that Adprt1a is required for NHEJ through PBZ domain–dependent retention of Ku at DSBs. Fig. S3 shows validation of disruption strains. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.201012132/DC1.

The adprt1b− strain was a gift from T. Cox and A. Kuspa. We are grateful to dicky Base and K. Colicelli for assistance.
