C oordination between functionally related adjacent tissues is essential during development. For example, formation of trunk neural crest cells (NCCs) is highly influenced by the adjacent mesoderm, but the molecular mechanism involved is not well understood. As part of this mechanism, fibroblast growth factor (FGF) and retinoic acid (RA) mesodermal gradients control the onset of neurogenesis in the extending neural tube. In this paper, using gain- and loss-of-function experiments, we show that caudal FGF signaling prevents premature specification of NCCs and, consequently, premature epithelial–mesenchymal transition (EMT) to allow cell emigration. In contrast, rostrally generated RA promotes EMT of NCCs at somitic levels. Furthermore, we show that FGF and RA signaling control EMT in part through the modulation of elements of the bone morphogenetic protein and Wnt signaling pathways. These data establish a clear role for opposition of FGF and RA signaling in control of the timing of NCC EMT and emigration and, consequently, coordination of the development of the central and peripheral nervous system during vertebrate trunk elongation.

Introduction

The neural crest is formed by a transient population of multipotent cells that arises from the dorsal neural tube. Once specified, neural crest cells (NCCs) undergo a process of epithelial–mesenchymal transition (EMT) that confers the ability to delaminate and migrate away from the dorsal neural tube. The NCCs migrate along characteristic pathways to differentiate into a wide variety of derivatives according to their rostro-caudal (R–C) position in the neural tube and to the order of emigration (Krispin et al., 2010). NCC derivatives include craniofacial skeleton, sensory neurons and glia, sympathetic neurons, and melanocytes, among others (Le Douarin and Kalcheim, 1999).

The process of neural crest formation implies the orchestration of a complex gene regulatory network (Morales et al., 2005; Sauka-Spengler and Bronner-Fraser, 2008). It involves signaling pathways and transcription factors that are responsible for the sequence of early induction of the NCC during gastrulation (Wnt, bone morphogenetic proteins [BMPs], FGF, and retinoic acid [RA]; Liem et al., 1995; Saint-Jeannet et al., 1997; Villanueva et al., 2002; Monsoro-Burg et al., 2003), the specification of the neural plate border (Msx1/2, Pax3, Pax7, and Zic1/3; Liem et al., 1995; Nakata et al., 1997; Brewster et al., 1998), the expression of bona fide NCC transcription factors (AP2, Snail1, FoxD3, Sox5, Sox9, and Sox10; Nieto et al., 1998; Dottori et al., 1994; Dottori et al., 2001; Kos et al., 2001; Paratore et al., 2001; Cheung and Briscoe, 2003; Barrallo-Gimeno et al., 2004; Perez-Alcala et al., 2004), and the regulation of numerous downstream effectors involved in cell adhesion and cell cycle control, among others (Sauka-Spengler and Bronner-Fraser, 2008).

Several neural crest specifier genes are coexpressed with neural plate border specifiers at early stages during gastrulation, suggesting possible early regulatory relationships (Khudyakov and Bronner-Fraser, 2009). However, this early population of neural crest progenitors mostly represents the cephalic NCCs, whereas the trunk neural crest progenitors will progressively be specified as the trunk neural tube elongates (Le Douarin and Kalcheim, 1999).

In that sense, the role of BMP, FGF, and Wnt signaling in the early NCC induction has been derived from work in *Xenopus laevis* at cephalic NCC territory. Thus, the signal-promoting trunk neural crest specification has not been fully elucidated.

The development of trunk NCCs is highly coordinated with the development of functionally related adjacent territories. In particular, flanking the neural tube, the paraxial or presomatic mesoderm (PSM) gets progressively segmented into smaller units, somites, and this metamORIZATION imposes a segmented organization to the trunk NCCs. First, opposite the PSM, NCCs are confined to the dorsal neural tube, whereas NCC emigration begins facing epithelial somites (Teillet et al., 1987; Sela-Donenfeld and Kalcheim, 1999). Moreover, the first indication of peripheral nervous system segmentation is the patterned ventral migration of NCCs through the anterior part of each somitic sclerotome (Tosney, 1978; Rickmann et al., 1985; Bronner-Fraser, 1986; Loring and Erickson, 1987).

There is little knowledge about the integration of signals involved in trunk NCC emigration. At trunk level, it has been shown that a BMP-Wnt1 signaling cascade controls NCC emigration (Sela-Donenfeld and Kalcheim, 1999; Burstyn-Cohen et al., 2004). The regulation of that cascade is exerted through the caudal (high)-rostral (low) gradient of the BMP inhibitor Noggin, which in turn is controlled by undetermined signals coming from somites (Sela-Donenfeld and Kalcheim, 2000).

In the paraxial mesoderm, the FGF and RA pathways operate as a signaling switch that controls the R-C sequence of mesodermal and neural development. Opposite gradients of declining caudal FGF and rostral RA signaling in the extending body axis create a wavefront, which determines the onset of neuronal differentiation and patterning in newly generated spinal cord (Diez del Corral et al., 2002, 2003) and also positions somite boundaries (Dubrulle et al., 2001; Diez del Corral et al., 2003). The trunk neural tube is generated during a long period of time as the main body axis extends caudally, and trunk neural crest is also generated after this R-C sequence. Thus, FGF and RA signaling control NCC EMT. In contrast, RA signaling triggers the EMT of specified NCCs. Furthermore, we show that FGF and RA signaling control the onset of trunk NCC specification and, consequently, NCC EMT. In contrast, RA signaling triggers the EMT of specified NCCs. Furthermore, we show that FGF and RA signaling control the timing of EMT and emigration in part through modulation of elements of the BMP and Wnt signaling pathways. Thus, opposition of FGF and RA signaling orchestrates the onset of trunk NCC specification and emigration, coordinating them with somite formation and neurogenesis in the extending vertebrate body axis.

**Results**

**Onset of NCC marker expression coincides with FGF8 decline**

To investigate whether the paraxial mesoderm has a general influence on NCC specification and migration in the spinal cord, we compared the expression patterns of a cohort of genes involved in dorsal patterning and NCC specification with respect to the formation of somites in chicken embryos at Hamburger and Hamilton (HH) stages 10–14 (Fig. 1, A–G). At the HH10 stage, the caudal open neural plate expressed dorsal patterning genes such as *Pax7* (Fig. 1 A; Kawakami et al., 1997), *Pax3* (not depicted; Goulding et al., 1991), *Rhob* (not depicted; Liu and Jessell, 1998), and *Msh1* (not depicted; Liem et al., 1995). This expression is maintained along the neural tube as the body axis extends (Fig. 1 A). More rostrally, when the neural folds move toward the midline to fuse, the expression of the NCC marker *Snail2* (Nieto et al., 1994) was found in the dorsal neural folds (Fig. 1 B) adjacent to the mid-PSM level. Subsequently, expression of *Sox* family genes involved in NCC formation could be observed in the dorsal neural tube. First, *Sox9* (Fig. 1 C; Cheung and Briscoe, 2003) appeared rostral to the initiation of *Snail2* and then *Sox5* (Fig. 1 D; Perez-Alcala et al., 2004). Finally, adjacent to forming somites, *Sox10* (Fig. 1 E; Paratore et al., 2001) was observed in premigratory NCCs about to emigrate.

This order in the expression of the genes described is maintained throughout stages HH12–14 (unpublished data). However, at HH10, *FoxD3*, an NCC specifier (Stewart et al., 2006), was not expressed dorsally in the neural folds (Fig. 1 F). Only by HH12 could *FoxD3* mRNA be observed at the rostral PSM level (Fig. 1 G).

The initiation of the expression of NCC markers seems to coincide with the transition zone where neural progenitors stop expressing caudal neural markers and initiate ventral patterning gene expression. This transition is governed by the opposing activities of the FGF and RA signaling gradients (Diez del Corral et al., 2003). In fact, by in situ hybridization of half embryos, we showed that the onset of *Snail2* expression coincided with the decline of the caudal neural gene *Sox1* expression (Fig. 1 H; Bertrand et al., 2000) and the appearance of the ventral patterning gene *Pax6* (Fig. 1 I; Bertrand et al., 2000). Moreover, the initiation of *Snail2* expression is close to the decay of *FGF8* transcripts in the neural tube (Fig. 1 K), and high levels of *Snail2* mRNA coincided with the onset of the RA-synthesizing enzyme *Raldh2* expression in the adjacent mesoderm (Fig. 1 J).

In summary, NCC markers are progressively transcribed in a precise temporal–spatial order in the presumptive region of premigratory NCCs. Moreover, these data suggest that the onset of specification and EMT of NCCs could be controlled by FGF and RA signaling gradients (Fig. 1 L).

**FGF signaling controls the onset of trunk NCC specification through the MAPK pathway**

FGF signaling is involved in the maintenance of the neural caudal stem zone, and it also represses neuronal differentiation and ventral patterning (Bertrand et al., 2000; Diez del Corral et al., 2003). To determine whether the onset of NCC specification was regulated by the decline of the caudal gradient of FGF8 signaling, we used the FGF receptor (FGFR) type 1 (FGFR1) antagonist SU5402 (Mohammadi et al., 1997). Cultured HH11 embryos exposed to this drug for 4 h exhibited a severe down-regulation of the well-known FGF signaling target *Sprouty2*.
This did not alter the onset of Snail2 expression ($n = 12/15$; Fig. S2) in relation to control DMSO-treated embryos ($n = 13/15$; Fig. S2). However, FGFR1 inhibition either with PD173074 or SU5402 did not alter the expression of FoxD3, another NCC specifier ($n = 4$ and $7$, respectively; Fig. S1 and not depicted), with respect to control embryos ($n = 9$).

Together, these results indicate that FGF caudal gradient prevents the premature expression of the early NCC specifier Snail2 in the caudal neural tube.

Activation of the tyrosine kinase FGFR can initiate transduction via several downstream pathways including MAPK and phosphatidylinositol 3-kinase (PI3K; Schönwasser et al., 1998). Both pathways have been involved in the transmission of FGF signaling during early stages of neural development (Ribisi et al., 2000; Stavridis et al., 2007), and dual phosphorylated MAPK has been specifically detected in the caudal FGF signaling domain (Lunn et al., 2007). We investigated the potential role of the MAPK kinase (MEK)–extracellular signal-regulated kinase (ERK) regulatory pathway in the control of NCC

Figure 1. The onset of expression of NCC markers along the R-C axis coincides with FGF8 decline. (A–K) Gene expression analysis of stages HH10 (A–F and H–K) and 12 (G) chicken embryos. Transverse sections at the last formed somite level (A–G'; indicated by horizontal lines in the corresponding figures). (H and I) Snail2 (H and I, left), Sax1 (H, right), or Pax6 (I, right) expression in bilaterally dissected embryos. (J and K) Double in situ hybridization for Snail2 (purple), Raldh2 (J, red), and FGF8 (K, red). Black arrowheads point to the last formed somite, and red arrows point to the border of gene expression. (L) Schema of the approximate axial level of different gene expression in relation to NCC development. Bars: (A, for A–G) 100 µm; (A', for A'–G' and A''–G'') 50 µm; (H, for H and I) 200 µm; (J, for J and K) 300 µm.

(n = 13/13; Fig. 2 B; Minowada et al., 1999) in comparison with control DMSO-treated embryos ($n = 0/12$; Fig. 2 A). After a 4-h culture with SU5402, Snail2 expression was enhanced in the dorsal part of the neural tube and was prematurely initiated at the level of Hensen’s node ($n = 11/12$; Fig. 2 F) in comparison with control embryos ($n = 4/18$; Fig. 2 E). A similar premature Snail2 up-regulation was observed using the specific FGFR1 inhibitor PD173074 ($n = 7/7$; Fig. S1; Skaper et al., 2000) and was quantified using quantitative RT-PCR as a twofold increase in relative Snail2 mRNA levels in PD173074 with respect to DMSO-treated samples in the neural tube at the level of the caudal PSM (2.06 [1.77–2.39]; Fig. S1).

As a control, a similar quantitative RT-PCR analysis showed a threefold decrease in Sprouty relative mRNA levels in PD173074 with respect to DMSO-treated samples (0.31 ± 0.16; Fig. S1). PD173074 and SU5402 not only inhibit FGFR signaling but also target VEGF receptors (VEGFRs; Mohammadi et al., 1997, 1998). To determine whether these effects are specifically mediated by FGFR signaling, we used a specific VEGFR inhibitor, KRN633 (Nakamura et al., 2004). This did not alter the onset of Snail2 expression ($n = 12/15$; Fig. S2) in relation to control DMSO-treated embryos ($n = 13/15$; Fig. S2). However, FGFR1 inhibition either with PD173074 or SU5402 did not alter the expression of FoxD3, another NCC specifier ($n = 4$ and $7$, respectively; Fig. S1 and not depicted), with respect to control embryos ($n = 9$).

Together, these results indicate that FGF caudal gradient prevents the premature expression of the early NCC specifier Snail2 in the caudal neural tube.
specification by selectively suppressing activation of MEK1 with the drug PD184352. In HH11 and 12 embryos cultured for 4 h, this drug effectively down-regulated the expression of a direct target of FGF signaling, Sprouty2 (n = 7/7; Fig. 2 C), and reduced ERK1/2 phosphorylation (92% decreased in phospho-ERK/relative to total ERK; n = 3; Fig. 2 I) in comparison with DMSO-treated embryos (n = 6; Fig. 2, A and I). As with inhibition of FGFR1, blockage of the MAPK pathway leads to a premature and enhanced caudal expression of the NCC specifier Snail2 (n = 4/4; Fig. 2 G). On the other hand, blockage of the PI3K pathway using the LY294002 treatment, which effectively reduces AKT phosphorylation (73% decreased in phospho-AKT/relative to total AKT; n = 3; Fig. 2 I), had very little effect on Sprouty2 (n = 1/7; Fig. 2 D; Echevarria et al., 2005) and on Snail2 mRNA expression (n = 0/4; Fig. 2 H). In conclusion, FGF signaling acting through the MAPK but not the PI3K pathway is required to prevent premature Snail2 expression in NCCs and, consequently, to delay NCC specification.

The FGF signaling pathway controls the initiation of trunk NCC emigration
Premature specification of NCCs could lead to premature emigration at axial levels previous to somite formation. In the aforementioned experiments, NCCs from embryos incubated with FGFR1 inhibitors for 4 h that prematurely expressed Snail2 were not able to emigrate, as assessed by the expression of Sox10 (n = 9; Fig. S1 and not depicted). To better test the consequence on NCC emigration, we examined the effect of blocking FGF signaling for longer periods of time using a dominant-negative FGFR1-EYFP protein (dn-FGFR1-EYFP; Yang et al., 2002) introduced into the right caudal hemitube at HH10 and 11. 18–20 h after electroporation, this construct effectively blocked the expression of FGF signaling targets such as Sprouty2 (n = 7/9; Fig. S3; Minowada et al., 1999) and induced Pax6 expression (n = 5/6; Fig. S3; Bertrand et al., 2000) in the neural tube in comparison with control pCIG embryos (n = 6 and 4/5, respectively; Fig. S3). Remarkably, dorsal neural progenitors expressing the dn-FGFR1-EYFP protein prematurely activated Snail2 (n = 4/4; not depicted) and Sox10 expression and exited the neural tube (n = 9/10; Fig. 3 B, arrowhead) in comparison with the control side or with cells electroporated with a control EGFP (n = 7; Fig. 3 A). Moreover, the progressive disruption of the basal lamina, identified by Laminin expression (Martins-Green and Erickson, 1987), was also more advanced in the side where FGF signaling had been blocked (n = 5/7; Fig. 3 F) with respect to the control side or control embryos (n = 7; Fig. 3 C).
significantly increased in FGFRdn embryos with respect to control pCIG (68 ± 28% in FGFRdn and 42 ± 15% in pCIG; Fig. S4 H). Interestingly, the relative number of GFP−Sox5+ cells was also significantly increased in FGFRdn embryos with respect to control pCIG (192 ± 61% in FGFRdn and 65 ± 7% in pCIG; Fig. S4 H). All these data suggest that the premature migration of the FGFRdn-GFP–electroporated cells was also promoting the exit of adjacent non-GFP NCCs, and, thus, the effect on FGFR blockage would be in part non–cell autonomous on NCCs.

Moreover, although NCC markers such as Sox10, Snail2, and Sox5 were prematurely expressed (Fig. 3 B and not depicted) and more ventrally expressed (Sox10; Fig. 3 B′), expression of dorsal markers such as Pax7 and Msx1 was not affected in the neural tube at epithelial somite levels (n = 6 and 10, respectively; Fig. 3, G and H). In conclusion, blocking FGF signaling in the neural tube adjacent to PSM promotes premature NCC specification and emigration from the neural tube.

To determine whether ectopically maintaining the FGF could prevent NCCs from delaminating, we placed FGF8/4-soaked beads in contact with the HH11 and 12 dorsal neural tube at a level in which NCCs have already been specified but before they start Sox10 expression. As expected, 18 h later, FGF4/8 promoted expression of its direct target Sprouty2 in the adjacent neuroepithelial cells in HH15–17 embryos (FGF8 n = 3 significantly increased in FGFRdn embryos with respect to control pCIG (68 ± 28% in FGFRdn and 42 ± 15% in pCIG; Fig. S4 H). Interestingly, the relative number of GFP−Sox5+ cells was also significantly increased in FGFRdn embryos with respect to control pCIG (192 ± 61% in FGFRdn and 65 ± 7% in pCIG; Fig. S4 H). All these data suggest that the premature migration of the FGFRdn-GFP–electroporated cells was also promoting the exit of adjacent non-GFP NCCs, and, thus, the effect on FGFR blockage would be in part non–cell autonomous on NCCs. Moreover, although NCC markers such as Sox10, Snail2, and Sox5 were prematurely expressed (Fig. 3 B and not depicted) and more ventrally expressed (Sox10; Fig. 3 B′), expression of dorsal markers such as Pax7 and Msx1 was not affected in the neural tube at epithelial somite levels (n = 6 and 10, respectively; Fig. 3, G and H). In conclusion, blocking FGF signaling in the neural tube adjacent to PSM promotes premature NCC specification and emigration from the neural tube.

To determine whether ectopically maintaining the FGF could prevent NCCs from delaminating, we placed FGF8/4-soaked beads in contact with the HH11 and 12 dorsal neural tube at a level in which NCCs have already been specified but before they start Sox10 expression. As expected, 18 h later, FGF4/8 promoted expression of its direct target Sprouty2 in the adjacent neuroepithelial cells in HH15–17 embryos (FGF8 n = 3 significantly increased in FGFRdn embryos with respect to control pCIG (68 ± 28% in FGFRdn and 42 ± 15% in pCIG; Fig. S4 H). Interestingly, the relative number of GFP−Sox5+ cells was also significantly increased in FGFRdn embryos with respect to control pCIG (192 ± 61% in FGFRdn and 65 ± 7% in pCIG; Fig. S4 H). All these data suggest that the premature migration of the FGFRdn-GFP–electroporated cells was also promoting the exit of adjacent non-GFP NCCs, and, thus, the effect on FGFR blockage would be in part non–cell autonomous on NCCs. Moreover, although NCC markers such as Sox10, Snail2, and Sox5 were prematurely expressed (Fig. 3 B and not depicted) and more ventrally expressed (Sox10; Fig. 3 B′), expression of dorsal markers such as Pax7 and Msx1 was not affected in the neural tube at epithelial somite levels (n = 6 and 10, respectively; Fig. 3, G and H). In conclusion, blocking FGF signaling in the neural tube adjacent to PSM promotes premature NCC specification and emigration from the neural tube.

To determine whether ectopically maintaining the FGF could prevent NCCs from delaminating, we placed FGF8/4-soaked beads in contact with the HH11 and 12 dorsal neural tube at a level in which NCCs have already been specified but before they start Sox10 expression. As expected, 18 h later, FGF4/8 promoted expression of its direct target Sprouty2 in the adjacent neuroepithelial cells in HH15–17 embryos (FGF8 n = 3
and FGF4 \( n = 4 \); Fig. 4, A and B; Minowada et al., 1999). In contrast to NCCs exposed to control BSA (Fig. 4, C and E, \( n = 3 \) and 5, respectively), the presence of FGF4/8 drastically reduced Sox10 (FGF4 \( n = 3/4 \) and FGF8 \( n = 3 \); Fig. 4 D) and Snail2 (FGF4 \( n = 4 \) and FGF8 \( n = 6 \); Fig. 4 F) expression and blocked NCC emigration. These data indicate that FGF maintains dorsal neural tube cells uncommitted with respect to neural crest fate and that FGF signaling decrease is necessary to promote NCC specification and subsequent migration from the neural tube.

### The timing of NCC emigration confers different migratory behavior

In the trunk region of avian embryos, NCCs migrate in a stereotypical manner, leading to a general ventral to dorsal order of derivative colonization beginning with sympathetic ganglia and, finally, melanocytes (Le Douarin and Kalcheim, 1999). The final localization of crest cells can be predicted from their relative ventrodorsal position within the premigratory domain or by their time of emigration (Henion and Weston, 1997; Krispin et al., 2010). However, it is also possible that distinct properties of the differentiated mesodermal cells that the NCCs encounter during migration influence their trajectories (Harris and Erickson, 2007).

To determine whether the NCCs prematurely forced to delaminate upon blockage of FGF signaling had alterations in their migratory behavior, we followed early NCC migration using wide-field real-time microscopy of trunk dorsal neural tubes in slice culture (Wilcock et al., 2007; Ahlstrom and Erickson, 2009). We used electroporation of H2B-RFP (nucleus)– and EGFP-glycosylphosphatidylinositol (GPI; cell membrane)–expressing vectors into stage HH10 chick embryos to follow individual cells (Fig. 5, A and C). Using MetaMorph software, we first compared the behavior of the migratory NCCs during the initiation or first wave of migration at the level of dissociating somites (somites V–XII) in control EGFP-GPI embryos (Fig. 5 [A, B, and G] and Video 1) in relation to dn-FGFR1-EYFP–electroporated NCCs that started prematurely migrating adjacent to epithelial somites (somites I–IV; Fig. 5 J and Video 3). We observed a similar speed of migration (16.2 ± 1.8 µm/h with respect to 12.4 ± 1 µm/h; Fig. 5 E) and a similar migration straightness (distance covered/length of the trajectory; 0.28 ± 0.07 with respect to 0.15 ± 0.03; Fig. 5, F and G) of the two spatially different located populations. These results indicate that the prematurely migrating NCCs, upon FGF signaling blockage, at epithelial somite levels have a similar behavior to the first wave of migrating control NCCs facing dissociating somites.

Conversely, we next analyzed the behavior of dn-FGFR1-EYFP–expressing NCCs (Fig. 5 [C, D, and H] and Video 2) that were migrating next to dissociating somites in comparison with the first migrating NCCs expressing EGFP-GPI (Fig. 5 A). The mean speed of the migratory NCCs upon a 12-h period was higher in NCCs expressing dn-FGFR1-EYFP (20.2 ± 1.9 µm/h; Fig. 5 E) with respect to control NCCs (12.4 ± 1 µm/h; Fig. 5, B and E). Moreover, tracking NCC trajectories revealed that most dn-FGFR1–expressing NCCs showed a straight trajectory (Fig. 5 H) contrary to control NCCs that exhibited tortuous trajectories and forward and backward movements (straightness factor of 0.39 ± 0.1 with respect to 0.15 ± 0.03; Fig. 5, F and G).
This higher speed and straightness of the more advanced delaminating NCCs expressing dn-FGFR1-EYFP could be a property of a more mature late-migrating NCC population in spite of both control and experimental cells facing the same somitic context. In summary, this analysis reveals distinct migratory properties according to the time of exit from the neural tube.

RA signaling is required to control the timing of NCC emigration

It has been shown that somites are required for the control of the onset of NCC emigration (Sela-Donenfeld and Kalcheim, 2000). However, the molecular nature of those signals emanating from the somites remains unknown. RA signaling is highly active in the neural tube at somitic levels, as revealed by in vivo reporter activity driven by RA response elements (RAREs) in mouse embryos (Rossant et al., 1991) and by the expression of a readout of RA signaling, RAR-β (the RARE promoter elements of which were used in the RARE-LacZ mouse) in chicken embryos (Olivera-Martinez and Storey, 2007). Moreover, the opposing gradients of FGF and RA pathways operate in concert as a switch that controls progressive neural and limb development (Diez del Corral and Storey, 2004).

To test whether RA could be involved in the control of NCC emigration in concert with FGF signaling, we performed neural tube electroporation of a truncated version of the human α-RA receptor (RAR [RAR-α]) that acts as a dominant-negative form for the three RARs (RARdn–internal ribosome entry site (IRES)–GFP; Novitch et al., 2003). As expected, blocking RAR signaling at HH12 and 13 decreased the expression of Pax6 in neural precursors 24 h after electroporation (Fig. S5; Novitch et al., 2003). In HH12 and 13 embryos in which RA signaling was blocked where NCC emigration was starting, the number of cells expressing Sox10 was reduced, and there was a dramatic delay in the emigration of Sox10+ NCCs (n = 5/5; Fig. 6 C) in comparison with the pCIG-electroporated cells (n = 5/5; Fig. 6 A). However, more caudally, the initiation of the expression of Snail2 and FoxD3, early markers of NCC specification, was not affected (n = 5 and 6, respectively; Figs. 6 F and S5) in comparison with control pCIG-electroporated embryos (n = 3 and 8, respectively; Fig. 6 E), indicating that RA is required to establish the onset of NCC emigration independently of NCC specification.

Nevertheless, in HH11–13 embryos electroporated at the level of ongoing NCC migration (somites V–X), RA signaling was blocked where NCC emigration was starting, the number of cells expressing Sox10 was reduced, and there was a dramatic delay in the emigration of Sox10+ NCCs (n = 5/5; Fig. 6 C) in comparison with the pCIG-electroporated cells (n = 5/5; Fig. 6 A). However, more caudally, the initiation of the expression of Sox10 was reduced, and there was a dramatic delay in the emigration of Sox10+ NCCs (n = 5/5; Fig. 6 C) in comparison with the pCIG-electroporated cells (n = 5/5; Fig. 6 A). However, more caudally, the initiation of the expression of Sox10 was reduced, and there was a dramatic delay in the emigration of Sox10+ NCCs (n = 5/5; Fig. 6 C) in comparison with the pCIG-electroporated cells (n = 5/5; Fig. 6 A). However, more caudally, the expression of Snail2 and FoxD3, early markers of NCC specification, was not affected (n = 5 and 6, respectively; Figs. 6 F and S5) in comparison with control pCIG-electroporated embryos (n = 3 and 8, respectively; Fig. 6 E), indicating that RA is required to establish the onset of NCC emigration independently of NCC specification.

To determine whether RA signaling was not only necessary but sufficient to control NCC emigration, we used a
at the rostral PSM level (Fig. 7 D) in comparison with normal embryos (Fig. 7 C). To determine how early RA signaling is required for NCC specification, Pax7 expression, a key mediator of neural plate border specification (Basch et al., 2006), was examined. In VAD embryos, Pax7 is absent at the neural plate border (Fig. 7 F) in comparison with normal quails (Fig. 7 E). As the VAD quails represent an early RA-deficient state, these findings suggest that RA signaling is required for the earliest steps in dorsal and NCC specification during gastrulation before the RA activity is restricted to the neural tube adjacent to rostral PSM and is not required for NCC specification during neural tube elongation.

FGF maintains Noggin gradient in the caudal neural tube

It has been reported that an R-C gradient of BMP signaling in the dorsal neural tube, generated by the graded expression of the BMP antagonist Noggin, is involved in determining the onset of NCC emigration (Sela-Donenfeld and Kalcheim, 1999). As the Noggin gradient is controlled by unknown signals coming from the mesoderm (Sela-Donenfeld and Kalcheim, 2000), we tested whether FGF and/or RA could be those signals. First, we determined whether FGF signaling was required for Noggin expression, as both coincide in the caudal neural tube (Figs. 1 K and 8 A). In cultured embryos at stages HH10 and 11 briefly exposed (4 h) to the FGFR1 inhibitor PD173074, Noggin expression in the neural tube

**Retinoid signaling is required for very early neural crest specification**

Our results have shown that RA signaling is not required for NCC specification during neural tube elongation. However, in Raldh2 mutants, the expression of early NCC markers is severely down-regulated (Ribes et al., 2009). To determine whether that was exclusive of mammalian embryos, we analyzed expression of neural crest markers in vitamin A–deficient (VAD) quails, which represent a retinoid-deficient state (Maden et al., 1996). In normal quails, Snail2 expression starts in the dorsal neural tube next to mid-PSM (Fig. 7 A), whereas it is strongly reduced in VAD NCCs (Fig. 7 B). Similarly, in RA-deficient conditions, Sox9 expression is clearly absent from the dorsal neural tube at the rostral PSM level (Fig. 7 D) in comparison with normal embryos (Fig. 7 C). To determine how early RA signaling is required for NCC specification, Pax7 expression, a key mediator of neural plate border specification (Basch et al., 2006), was examined. In VAD embryos, Pax7 is absent at the neural plate border (Fig. 7 F) in comparison with normal quails (Fig. 7 E). As the VAD quails represent an early RA-deficient state, these findings suggest that RA signaling is required for the earliest steps in dorsal and NCC specification during gastrulation before the RA activity is restricted to the neural tube adjacent to rostral PSM and is not required for NCC specification during neural tube elongation.
In summary, these results indicate that RA does not control NCC emigration through the down-regulation of *Noggin* gradient. Moreover, FGF signaling is sufficient but not necessary for *Noggin* expression, suggesting that the decrease in FGF signaling is required for *Noggin* down-regulation at somitic levels.

**FGF and RA regulate NCC emigration in part through the control of *Wnt1* expression**

It has been reported that Wnt ligands are necessary to control Snail2 expression in NCCs in vivo and are sufficient to induce NCCs by in vitro assays (García-Castro et al., 2002). Moreover, blocking canonical Wnt signaling prevents NCC emigration (Burstyn-Cohen et al., 2004). However, apart from the control by BMP signaling (Burstyn-Cohen et al., 2004), the regulation of the Wnt pathway has not been extensively analyzed in the NCC during axial elongation. We looked to determine whether at NCC emigration FGF and RA signaling could be acting through the modulation of *Wnt1*.

In cultured embryos at stages HH12–14 briefly treated (4 h) with the FGFR1 inhibitor PD173074, the R-C gradient of *Wnt1* expression was prematurely initiated at more caudal levels (control: n = 10; Fig. 9 B) relative to control DMSO-treated embryos (control: n = 7; Fig. 9 A). Conversely, exposing neural tube explants from rostral PSM levels to FGF4 for 4 h in culture inhibited *Wnt1* expression (FGF4: n = 6; BSA: n = 8; Fig. 9, C and D; described for longer incubation times in Olivera-Martinez et al., 2002). Thus, the caudo-rostral FGF signaling gradient is sufficient but not necessary for *Noggin* expression.

To test whether RA was the signal responsible for repression of *Noggin* transcription, RARdn was electroporated in NCCs adjacent to rostral PSM. RARdn-electroporated NCCs exhibited similar levels of *Noggin* expression (n = 4; Fig. 8 D) to that of control (n = 3; Fig. 8 C). Similarly, in trunk explants at the caudal PSM level exposed for 4 h to the RAR agonist TTNPB, which induced high levels of *Pax6* (TTNPB n = 10; control n = 9; Fig. 8, M and N; Novitch et al., 2003), *Noggin* expression was similar to that in control DMSC-treated explants 4 and 8 h after culture (control, 4 h, n = 10; TTNPB, 4 h, n = 12; control, 8 h, n = 4; TTNPB, 8 h, n = 4; Fig. 8, O and P).
In summary, FGF signaling prevents the premature expression of \textit{Wnt1}, whereas RA signaling triggers the initiation of \textit{Wnt1} expression in the dorsal neural tube only at levels in which the NCCs are already specified. Given the short time required for its action in culture, FGF and RA could control the timing of NCC emigration through direct changes in \textit{Wnt1} expression.

**Discussion**

During embryonic development, it is essential to coordinate the formation of adjacent tissues that maintain close functional relationships. In this work, we have established the mechanism that ensures the correct coordination between the formation of the central and peripheral nervous system in the trunk during the extension of the body axis. We have demonstrated that FGF and RA signaling set the correct timing for the crucial step of NCC EMT and emigration, which is necessary for the distribution of peripheral nervous system progenitors along the body axis. We have demonstrated that FGF and RA signaling are required for the control of \textit{Wnt1} expression in the dorsal neural tube, whereas RA signaling triggers the initiation of \textit{Wnt1} expression in the dorsal neural tube only at levels in which the NCCs are already specified. Given the short time required for its action in culture, FGF and RA could control the timing of NCC emigration through direct changes in \textit{Wnt1} expression.
Xenopus embryos concern the cephalic NCCs (Monsoro-Burq et al., 2003; Hong and Saint-Jeannet, 2007), our work shows that the FGF pathway is, so far, the only signaling pathway clearly controlling the onset of NCC specification at the trunk level. This FGF function could be another example of a general FGF role in controlling the onset of differentiation of all cell types, as they are generated at the tail end.

Our study also points out the relevance of controlling Snail2 expression to initiate NCC specification. Not only is Snail2 expression ectopically activated just after 4 h of FGF signaling blockage in comparison with FoxD3, which remained unchanged, but Snail2 is also one of the earliest NCC specifier genes being expressed during trunk NCC formation (Fig. 1; this study) and also during the caudal-most NCC development (caudal vertebrae level) in which Snail2 expression also precedes that of Sox9 and FoxD3 (Osório et al., 2009). The regulation of Snail gene expression by FGF seems to be context dependent during development. Although Snail1 is induced by FGF8 in the lateral mesoderm (Boettger et al., 1999) and primitive streak (Ciruna and Rossant, 2001) and by FGF3 in bone development (de Frutos et al., 2007), it is repressed by FGF in the somites (Boettger et al., 1999), and Snail2 is repressed in the dorsal neural tube (this study). Furthermore, controlling the right levels of FGF signaling is essential to modulate Snail gene expression. In Xenopus embryos, FGF signaling is involved in cephalic NCC induction (Monsoro-Burq et al., 2003). However, an excess of FGF signaling inhibits Snail2 expression and NCC formation (Hong and Saint-Jeannet, 2007).

Figure 9. Onset of Wnt1 expression is controlled by both FGF and RA signaling. (A and B) Stage HH11 and 12 embryos cultured for 4 h in the presence of DMSO (control) or FGFR1 inhibitor (PD173074) and analyzed for the expression of Wnt1. Arrows point to the onset of expression in the neural tube. (C–F) Explants of neural tube adjacent to rostral PSM (C and D) or whole trunk (including neural tube and mesoderm; E and F) cultured for 4 h in the presence of PBS-BSA (C) or DMSO (E) as a control, FGF8 (D), or the RA agonist TTNPB (F) and analyzed for Wnt1 expression. (G–J) Comparison of Wnt1 (G and H) and Wnt3a (I and J) expression in VAD quails and control stage matched quail embryos (wild type [WT]). (G’–J’) Transverse sections at the level are indicated by horizontal lines in G–J. Black arrowheads point to the last formed somites. Bars: (A, for A and B) 160 µm; (C, for C and D) 50 µm; (E, for E and F) 42 µm; (G, for G–J) 100 µm; (G’, for G’–J’) 50 µm.
Figure 10. Signaling pathways involved in the control of NCC specification and emigration during trunk elongation. The FGF signaling (pink), acting through the MAPK pathway, prevents the onset of NCC (green) specification in the caudal neural tube and, through the regulation of Wnt1 onset of expression (pale red) and Noggin (orange) expression, controls the initiation of NCC emigration. The RA signaling (blue) controls the initiation of NCC emigration by modulating NCC genes (dashed arrow) or by controlling the onset of Wnt1 expression (gray lines; data from Burstyn-Cohen et al., 2004).

In contrast to FGF signaling acting at the caudal level, RA signaling is operating at somitic levels. Our data demonstrate that, at least during trunk elongation, RA signaling is not required for the control of NCC specification but regulates the timing of NCC emigration. Thus, the onset of Snail2 expression is not affected by changes in RA signaling, but the onset of emigration of Sox10+ NCC cells at the midrostral PSM level can be modulated by changing RA signaling.

BMP activity regulates emigration of already specified NCCs (Sela-Donenfeld and Kalcheim, 1999) through the control of Wnt1 expression (Burstyn-Cohen et al., 2004). RA activity controls emigration modulating, together with FGF signaling, the onset of Wnt1 expression in the dorsal neural tube at rostral PSM levels (Fig. 10). Thus, our experiments have established that both FGF and RA signaling act as upstream pathways to the BMP/Noggin-Wnt1 signaling cascade to set the right timing for NCC emigration to keep it in register with somite formation. However, the effect of RA on emigration only occurs at rostral PSM and the last-formed somite level. More rostrally, inhibiting RA signaling does not affect ongoing emigration probably because BMP signaling is sufficient to maintain the process (Burstyn-Cohen et al., 2004). Conversely, at most, caudal neural tube level changes in FGF or RA signaling are not sufficient to induce premature Wnt1 expression (Fig. 9), and, consequently, NCCs cannot delaminate from the most caudal part of the neural tube. This time, the absence of BMP signaling at caudal levels could be responsible for the impossibility of emigration.

The consequences of altering the timing of migration could be crucial for the development of the NCC derivatives. It has recently been shown that the final localization of crest cells can be predicted by their time of emigration (Krispin et al., 2010). Here, we have demonstrated that the different NCC populations do differ in their migratory behavior, as the first migratory cells (including those prematurely forced to migrate in our experiments; Fig. 5) move at lower speed and follow more tortuous paths than later-migrating NCCs. It remains to be seen whether changes in migratory behavior adopted in an inappropriate context (nondifferentiated somites) will have consequences in the final differentiation of the NCCs.

In summary, our data show that there is a limited time window during which the onset of the NCC emigration can be modulated once those cells have acquired the expression of the essential gene network of the NCC specification program. That window coincides with the region where FGF and RA gradients collide, and it is required to keep the emergence of peripheral nervous system progenitors in register with the progressive programs of spinal cord neurogenesis and somite development during trunk axial elongation.

Materials and methods

In situ hybridization
Chicken eggs were incubated at 38 °C in an atmosphere of 70% humidity. Embryos were fixed overnight at 4°C with 4% PFA in PBS, rinsed, and processed for whole-mount in situ hybridization. In brief, embryos were treated with 1% H2O2 and 10 µg/ml proteinase K, refixed in 4% PFA, and then hybridized overnight at 57°C in 5x SSC buffer containing 50% formamide with digoxigenin- or fluorescein-labeled riboprobes as previously described (Martinez-Morales et al., 2010). The chick Pax7, Snail2, Sox5, Sox10, FoxD3, Sox9, Pax6, Radh2, FGF8, Sprouty2, Noggin, and Wnt1 riboprobes have been previously described (Cheung and Briscoe, 2003; Diez del Corral et al., 2003; Burstyn-Cohen et al., 2004; Perez-Alcala et al., 2004). Chicken Pax3 and Pax7 cDNAs were provided by H. Nakamura (Tokohu University, Sendai, Japan). Chicken VE-cadherin was cloned using primers 5'-TCCCCATATGCTCTCA-TCTCTGAAG-3' (forward) and 5'-TGCCCTCTCCCAAACCTTACCTCC3' (reverse) following recommendations from C.A. Roselló (Centro Nacional de Investigaciones Cardiovasculares, Madrid, Spain). 4–15 embryos were analyzed for each experimental condition. The probe hybridization was detected with AP coupled with either antidigoxigenin Fab fragments (Roche) or antifluorescein Fab fragment (Roche) and developed with nitro blue tetrazolium chloride/5-bromo-4-chloro-3-indolylphosphate p-toluidine salt (BCIP) or 2-[4-iodophenyl]-5-[4-nitrophenyl]-3-phenyltetrazolium chloride/BCIP. Hybridized embryos were postfixed in 4% PFA and vibratome sectioned, and immunostaining was performed as described in the Immunohistochemistry section to visualize GFP-electroporated cells.

Embryo and explant culture
Chicken embryos at stages HH11 and 12 were cultured onto collagen beds (prepared as a mixture containing 2.9 mg/ml collagen rat tail [BD], 1x l15 [Invitrogen], and 0.6% NaHCO3 to achieve proper polymerization)
covered with Opti-MEM medium (Invitrogen) supplemented with 5% FBS serum, 2 mM glutamine, and 50 μg/ml gentamycin. Inhibitors were added to the culture medium (100 μM U0126, 100 μM PD184352, 10 μM PD173074, 100 μM LY294002, 10 μM KRN633, or DMSO vehicle). Embryos were cultured for 4 h at 37°C and 5% CO2 before fixation in 4% PD173074, 100 μM LY294002, 10 μM KRN633, or DMSO vehicle). Embryos were cultured in early chick culture (Chapman et al., 2001) before being grafted with heparin-coated beads soaked in PBS, FGF8b (50 μg/ml), or FGF4 (50 or 500 μg/ml; an inducer of MAPK-like FGF8; Sigma-Aldrich; Diez del Corral et al., 2002; Casanova et al., 2011). Both FGF4 and FGF8 provoked a decrease in the expression of Snail2 and Sox10, but, obviously, the effect was more extensive with the highest concentration, affecting a larger area of premyogenic NCCs (Casanova et al., 2011). After incubation at 38°C for 18–20 h, embryos were either processed for whole-mount in situ hybridization or dissected to obtain explants for quantitative RTPCR. Receptor-deficient quail embryos were a gift from E. Gale and M. Maden (Medical Research Council Centre for Developmental Neurobiology, King’s College London, London, England, UK), and normal and deficient quail embryos were fixed and processed together for in situ hybridization (Diez del Corral et al., 2003).

Explants were dissected from HH9–13 embryos treated with trypsin to separate the neural tissue from the mesoderm when necessary (Diez del Corral et al., 2002). Explants were cultured in collagen beads and cultured covered in Opti-MEM medium as described above containing either BSA or 360 ng/ml FGF4 (both supplemented with 0.1% of 10 μg/ml heparin) or containing 10 μM KRN633 (EMD), 0.1% DMSO, or 10 μM TNP8 (EMD).

Western blot analysis
Western blot analysis was performed by an established method. 20 μg protein samples of each total cell extract were separated by 12% SDS-PAGE, transferred to a polyvinylidene fluoride Immobilon-P membrane (Millipore), and probed with antibodies antiphospho-AKT (rabbit IgG, Cell Signaling Technology), antianti-AKT1/2 (anti-H16; Santa Cruz Biotechnology, Inc.), anti-phospho-Erk1/2 (Thr202/Tyr204; Cell Signaling Technology), and anti-anti-Erk1/2 (Invitrogen). Signals were detected with HRP-conjugated secondary antibodies (Jackson ImmunoResearch Laboratories, Inc.) using an ECL Advance Western Blotting Detection kit (GE Healthcare). Quantitative analysis was obtained with a densitometer (GS-800, Bio-Rad Laboratories). Results shown are representative of three or more experiments.

Quantitative real-time PCR
Explants of neural tube together with notochord at caudal PSM levels were dissected from embryos cultured for 4 h in the presence of DMSO or PD173074, and total RNA was isolated using the QuickGene RNA tissue isolation kit (FUJIFILM). cDNA was synthesized with SuperScript III DNA polymerase (Invitrogen) and random primers (Invitrogen). Real-time PCR was performed in a 7500 PCR System using Power SYBR green Master Mix (Applied Biosystems) and sequence-specific primers (Sigma-Aldrich). Sequences of Snail2 primers were 5′-AGGCAAATCACTAAGGAAG-3′ (forward) and 5′-TGATAGGGACTGGGTAGCTTTC-3′ (reverse), and sequences for Sprouty2 primers were 5′-ATGTAGACTGCTGCTCATCTC-3′ (forward) and 5′-TGCTCCCAAGTCTCTTGGC-3′ (reverse). 18S ribosomal RNA was used as a reference gene. Sprouty2 levels were determined using the standard curve method, whereas Snail2 levels were determined by the comparative Ct method following recommendations by Applied Biosystems based on validation experiments assessing whether efficiencies of target and reference genes are approximately equal. Three lots of 4–12 explants generated in three independent experiments were used. Each of these samples was retrospectively analyzed, the product was used as a template for each pair of primers in triplicate-well PCR reactions, and the PCR procedure was performed twice.

Constructs
Truncated chick FGFR1c (aa 1–425) fused to EYFP in a Clontech vector (pEYFP-N1) to generate Δ-FGFR1cEYFP was provided by C. Weijer (University of Dundee, Dundee, Scotland, UK; Yang et al., 2002) and was also inserted into pCAGGS-IRES-nuclear EGFP (pcig; Niwa et al., 1998) to generate pCIG-FGRFRdn. The pCAGGS vector containing a membrane-associated EGFP-GPI was used as a control. cDNAs encoding human RARα truncation mutant 403 (RAR403; Damm et al., 1993) and a VP16-RARα fusion (Castro et al., 1999) cloned into pCIG were provided by B. Novitch (University of California, Los Angeles, CA; Novitch et al., 2003). In this case, pCIG was used as a control vector.

Chick in ovo electroperoration
Chick embryos were electroporated with purified plasmid DNA (QIAGEN) at 1–2 μg/ml in PBS with 50 ng/ml Fast green, as previously described (Martinez-Morales et al., 2010). In brief, plasmid DNA was injected in the lumen of HH10 and 12 neural tubes, electrodes were placed on either side of the neural tube, and a train of electric pulses (five pulses at 14 V for 50 ms) was applied using an electroporator (TSS20; Intracel). Eggs were further incubated for 24–48 h and were assayed for EGFP expression in the neural tube. Subsequently, the embryos were fixed and processed for immunohistochemistry or in situ hybridization.

Immunohistochemistry
Embryos were fixed for 2–4 h at 4°C with 4% PFA in PBS, and they were immersed in 30% sucrose solution, embedded in optimal cutting temperature medium, and sectioned on a cryostat (CM1900; Leica). Alternatively, embryos were embedded in 5% agarose/10% sacarose and were sectioned in a vibratome (VT1000FS; Leica). For immunohistochemistry, 10-μm cryostat or 40-μm vibratome agarose sections were permeabilized with 0.5% Triton X-100, blocked with 10% PBS, and incubated overnight at 4°C with the primary antibody. After washing, the cryostat sections were incubated for 1 h with secondary antibodies. Primary antibodies against the following proteins were used: Sox5 (Perez-Alcala et al., 2004); GFP (Invitrogen), and Laminin (Sigma-Aldrich). Monoclonal antibodies against Pax7, Mx1 (4G1), Pax6, AP2 (385), Pax3, and Snail (62.1E6) were all obtained from the Developmental Studies Hybridoma Bank (developed under the auspices of the National Institute of Child Health and Development and maintained by the University of Iowa). Alexa Fluor 488– and Cy3-conjugated anti–mouse or –rabbit secondary antibodies (Invitrogen) were used for detection, and, after staining, the sections were mounted in Citifluor mounting medium plus bisbenzimide and photographed using a true confocal scanner microscope (SP5; Leica).

Real-time imaging
Embryos at stages HH10 and 11 were electroperorated with a concentration of 0.2 μg/μl H2B-EFP either with 1 μg/μl GFP-GPI orΔ-FGFR1c-EYFP. Embryos were incubated at 38°C for 18 h (for imaging at stages HH15 and 16). Slices of ~150 μm were taken from the trunk on stage HH16–18 chicken embryos (Wilcock et al., 2007) at the axial level of caudal, epipodial (somite 1–IV), or rostral dissociated (somite V–XII) somites. Explants were cultured as described by Wilcock et al. (2007). In brief, slices of ~150 μm were taken with a microknife, embedded in rat tail collagen type I in cover-slip-based Petri dishes (Willco glass-bottom dish [Intracel] and GWs3522 coaled with poly-L-lysine [Sigma-Aldrich]), and cultured in Neurobasal medium without phenol red (Invitrogen) and supplemented with B27 to a final 1x concentration with glutamine and gentamycin maintained at 37°C with 5% CO2/air for ~4 h before imaging. Slices were imaged on a microscope workstation (DeltaVision Core; Applied Precision; Wilcock et al., 2007). The images were deconvolved and projected using DeltaVision software (softWoRx, Applied Precision). Metamorph software (Molecular Dynamics) was used to analyze the neural crest trajectory and the speed of migration. For each experimental condition, 10 cells were analyzed during a period of 4–12 h from at least four embryos.

Image acquisition and processing
Transmitted light images were acquired in an upright microscope (Eclipse 80i; Nikon) with Digital Sight DS-U1 or DXM1200F cameras using ACT-1 or ACT-2u software (Nikon). Whole embryos and explants were mounted in 50% PBS/50% glycerol and photographed with 10x/0.3 Plan Fluor, 20x/0.75 Plan Apo, or 20x/0.5 Plan Fluor objectives. Vibratome sections were mounted in 50% PBS/50% glycerol and photographed with a 40x/0.75 Plan Fluor objective. Fluorescence-labeled sections were mounted in Citifluor mounting medium plus bisbenzimide, and confocal images were taken using a true confocal scanner system (SP5; Leica) and a 40x/1.40 oil UV-corrected objective. Fluorochromes used were bisbenzimide (Invitrogen), Alexa Fluor 488 (Invitrogen), and Cy3 (Jackson Immunoresearch Laboratories, Inc.). Images were assembled and corrected in contrast and brightness using Photoshop (CS3; Adobe).

Figure S1. Analysis of NCC specification and emigration upon FGFR blockage using the PD173074 inhibitor. (A–H) Chicken embryos at stages HH11 and 12 were cultured for 4 h in the presence of control (DMSO) or pharmacological inhibitors for FGFR1 (PD173074) and were analyzed for the expression of Sprouty2 (A and B) as a control and for Snail2 (C and D), FoxD3 (E and F), and Sox10 (G and H). Black arrowheads point to the last formed somite, white arrows point to the caudal level of Snail2 expression in the neural tube, and black arrows point to the most caudal level of gene expression in the neural tube. Bar, 200 µm. (I) Relative mRNA levels of Sprouty and Snail2 in explants of neural tube together with notochord taken at caudal PSM levels obtained from embryos cultured for 4 h. In the presence of PD173074, Sprouty levels decreased, and Snail2 levels increased with respect to control samples (DMSO treated). Levels were determined by quantitative RT-PCR and normalized to 18S ribosomal RNA. Error bars indicate SD for Sprouty (standard curve method) and $2^{-\Delta\Delta Ct} \times SD$ for Snail2 (comparative Ct method; see Materials and methods). Three lots of 4–12 explants generated in three independent experiments were used. Significant differences were tested by a Student’s t test. *, $P < 0.05$.

Figure S2. VEGFR activity inhibition does not alter Snail2 expression in the neural tube. (A and B) Chicken embryos at stages HH11 and 12 were cultured for 4 h in the presence of control (DMSO; A) or pharmacological inhibitors for VEGFR (KRN633; B) and analyzed for the expression of Snail2. (C and D) Trunk explants at the level of rostral PSM from HH13 and 14 embryos were cultured for 24 h in the presence of DMSO (n = 7; C) or KRN633 (n = 8; D) and analyzed for VE-cadherin expression. Black arrowheads point to the last formed somite, and white arrows point to the caudal level of Snail2 expression. Bars: (A and B) 150 µm; (C and D) 70 µm.
Figure S3. **Blockage of the FGF signaling pathway promotes premature Pax6 expression and prevents Sprouty2 expression in the neural tube.** (A–D) Stage HH11–13 embryos electroporated on the right neural hemitube with control (EGFP-GPI; A and C) or a dominant-negative truncated version of FGFR1 fused to EYFP (dnFGFR1-EYFP; B and D) construct and analyzed 18–24 h later for Pax6 expression (A and B) and Sprouty2 expression (C and D). Black arrowheads point to the last formed somite, and brackets indicate the electroporated area. (A–D) Transverse sections at the level indicated by horizontal lines in the corresponding figures. Bars: (A, for A–D) 45 µm; (A’, for A’–D’) 30 µm.
Figure S4. **Blockage of the FGF signaling pathway promotes NCC premature emigration of several populations.** (A–F) Stage HH11–13 embryos electroporated on the right neural hemitube with control pCIG or a dominant-negative truncated version of FGFR1 in pCIG (pCIG-FGFRdn) construct and analyzed 18–24 h later. Immunostaining in electroporated embryos showing in red Sox5 (A and D), Ap2 (B and E), and Pax7 (C and F) expression. (A–F) EGFP expression in the electroporated hemitube. White arrows in D point to double GFP+ Sox5+ cells. Observe that there is a high number of migratory Sox5+ cells that are GFP−. Bar, 30 µm. (G) Quantification of the number of cells in the electroporated area that expresses a marker with respect to the cells expressing the same marker in an equivalent area in the nonelectroporated side. (H) Quantification of the relative number of migratory Sox5+ cells that are either GFP+ or GFP− with respect to the number of Sox5+ migratory cells in the control nonelectroporated side (as a way of normalization to reduce axial level variations) in both pCIG- or FGFRdn-electroporated embryos. Quantitative data were expressed as the mean ± SD of n ≥ 4 embryos (and at least four sections per embryo) per experimental point. Significant differences were tested by a Student's t test. *, P < 0.05; **, P < 0.01; ***, P < 0.001.
Figure S5. RA signaling is not required to maintain NCC emigration and does not control the onset of FoxD3 expression in the neural tube. (A–D) Chicken embryos at stages HH11–13 were electroporated on the right neural hemitube with control pCIG construct or a dominant-negative truncated version of RAR-α in pCIG (RARdn) at rostral somitic levels and analyzed 18–24 h later. The white dotted lines outline the neural tube borders. (A and C) Immunostaining for Pax6 showing a clear reduction in pCIG-RARdn-electroporated neuroepithelial cells. (B and D) AP2+ pre- and migratory NCCs are not affected by the blockage in the RA signaling pathway. (A′–D′) GFP-electroporated areas. (E–G) Chicken embryos at stages HH11–13 electroporated on the right neural hemitube with control pCIG, RARdn, or a constitutively active form of RAR-α (RAR-VP16) and analyzed 18–24 h later for FoxD3 expression. Black arrowheads point to the last formed somites, and brackets indicate the electroporated area. (E′–G′) Transversal sections at the level are indicated by horizontal lines in the corresponding figures. Bars: (A, for A–D) 25 µm; (E, for E–G) 180 µm; (E′, for E′–G′) 40 µm.

Video 1. Migration of NCCs electroporated with H2B-RFP and with control EGFP-GPI at the level of differentiating somites (V–XII somites). H2B-RFP, red; EGFP-GPI, green. Cells were imaged by time-lapse microscopy using a DeltaVision Core microscope, and images were taken at 7-min intervals. A total of 104 frames were taken during 12 h.

Video 2. Migration of NCCs electroporated with H2B-RFP and with dn-FGFR1-EYFP at the level of differentiating somites (V–XII somites). H2B-RFP, red; dn-FGFR1-EYFP, green. Cells were imaged by time-lapse microscopy using a DeltaVision Core microscope, and images were taken at 7-min intervals. A total of 63 frames were taken during 7.5 h.

Video 3. Migration of NCCs electroporated with H2B-RFP and with dn-FGFR1-EYFP at the level of epithelial somites (I–IV somites). H2B-RFP, red; dn-FGFR1-EYFP, green. Cells were imaged by time-lapse microscopy using a DeltaVision Core microscope, and images were taken at 7-min intervals. A total of 99 frames were taken during 12 h.
