Forms associate with other nucleators and nucleation-promoting factors (NPFs) to stimulate collaborative actin assembly, but the mechanisms regulating these interactions have been unclear. Yeast Bud6 has an established role as an NPF for the formin Bni1, but whether it also directly regulates the formin Bnr1 has remained enigmatic. In this paper, we analyzed NPF-impaired alleles of bud6 in a bni1/lin background and found that Bud6 stimulated Bnr1 activity in vivo. Furthermore, Bud6 bound directly to Bnr1, but its NPF effects were masked by a short regulatory sequence, suggesting that additional factors may be required for activation. We isolated a novel in vivo binding partner of Bud6, Yor304c-a/Bil1, which colocalized with Bud6 and functioned in the Bnr1 pathway for actin assembly. Purified Bil1 bound to the regulatory sequence in Bud6 and triggered NPF effects on Bnr1. These observations define a new mode of formin regulation, which has important implications for understanding NPF-nucleator pairs in diverse systems.

Introduction

The assembly of filamentous actin arrays is a tightly regulated process in cells and requires the convergence of multiple signaling pathways to activate machinery that directly stimulates actin filament nucleation and elongation (Heasman and Ridley, 2008; Pollard and Cooper, 2009; Padrick and Rosen, 2010). Several actin nucleators and their cofactors or nucleation-promoting factors (NPFs) have been identified (Pollard, 2007; Chesarone and Goode, 2009; Dominguez, 2009; Firat-Karalar and Welch, 2011). These nucleators and NPFs often work together in pairs to overcome cellular barriers to actin assembly (Blanchon and Michelot, 2012; Breitsprecher et al., 2012). Perhaps the best understood nucleator-NPF pair is the Arp2/3 complex and its actin monomer-binding cofactor Wiskott–Aldrich syndrome protein, which is tightly regulated on multiple levels (Dominguez, 2010; Rottner et al., 2010). Formins have also recently been shown to work with other nucleators and NPFs (Quinlan et al., 2007; Okada et al., 2010; Graziano et al., 2011; Blanchon and Michelot, 2012; Block et al., 2012; Breitsprecher et al., 2012), but far less is known about the regulation and molecular basis of these interactions.

Formins are large signal-responsive proteins that promote actin assembly using their C-terminal halves. The FH2 domain is required and sufficient for nucleation (Pruyne et al., 2002; Sagot et al., 2002b) and forms a flexibly tethered homodimer that binds with high affinity to the barbed ends of filaments (Pruyne et al., 2002; Zigmold et al., 2003; Moseley et al., 2004; Xu et al., 2004; Otomo et al., 2005). Nucleation by the FH2 domain can be strongly enhanced by the adjacent actin monomer-binding C-terminal tail regions, which often contain diaphanous autoregulatory domain (DAD) and/or WH2 domains (Gould et al., 2011; Vizcarra et al., 2011; Heimsath and Higgs, 2012). After nucleation, the dimeric FH2 domain processively tracks the growing barbed end of the filament, protecting it from capping proteins (Zigmond et al., 2003; Kovar and Pollard, 2004; Moseley et al., 2004; Breitsprecher et al., 2012). On the N-terminal side of the FH2 domain is the FH1 domain, which delivers profilin-bound actin monomers to the growing barbed end to accelerate elongation (Romero et al., 2004; Kovar et al., 2006; Vavylonis et al., 2006; Courtemanche and Pollard, 2012).

To date, formins have been shown to physically associate with three other nucleators or NPFs: Spire and adenomatous polyposis coli (APC) in metazoans and Bud6 in fungi. APC and Dia (Diaphanous) colocalize and interact in developing Drosophila melanogaster embryos, in which they are both required for actin-based ingestion of pseudocleavage furrows (Webb et al., 2009).

Abbreviations used in this paper: APC, adenomatous polyposis coli; BBS, Bud6 binding site; DAD, diaphanous autoregulatory domain; NPF, nucleation-promoting factor; NTA, nitrilotriacetic acid; RMA, rabbit skeletal muscle actin; TEV, tobacco etch virus; TIRF, total internal reflection fluorescence; TIRF-M, TIRF microscopy.
Figure 1. Bud6 NPF activity is required in vivo for proper actin cable assembly by Bnr1. (A and B) 10-fold serial dilutions of yeast strains grown at 25 and 37°C on YEPD plates. (C) F-actin staining of the indicated strains. Cells were grown to log phase at 25°C in YEPD, fixed, and stained with Alexa Fluor 488–phalloidin. The image containing the bni1Δbud6-35 strain is a composite of three individual images. Bar, 5 µm. (D and E) Quantification
Corroborating this genetic relationship, vertebrate APC and mDia1 directly interact in vitro and together stimulate actin assembly by a "rocket launcher" mechanism (Wen et al., 2004; Okada et al., 2010; Breitsprecher et al., 2012). Spire colocalizes and interacts with the formin Fmn2/Capu in both Drosophila and mouse oocytes and is required for Fmn2/Capu-dependent assembly of actin meshworks (Pfender et al., 2011; Schuh, 2011). However, the mechanism underlying their collaboration is still poorly understood, as purified Spire inhibits rather than enhances the activity of Fmn2/Capu in vitro (Quinlan et al., 2007; Vizcarra et al., 2011). In yeast, Bud6 and the formin Bnl1 colocalize and interact at polarity sites, where they collaborate to promote actin cable assembly (Amberg et al., 1997; Segal et al., 2000), and purified Bud6 and Bni1 interact in vitro to stimulate actin nucleation (Moseley et al., 2004; Moseley and Goode, 2005; Graziano et al., 2011). Thus, although these formin-binding nucleators or NPFs exhibit no obvious sequence homology, they share key properties: each binds to the tail region of a formin, each binds with high affinity to multiple actin monomers, and each promotes actin nucleation without significantly altering the rate of elongation (Bosch et al., 2007; Quinlan et al., 2007; Pechlivanis et al., 2009; Okada et al., 2010; Graziano et al., 2011; Sitar et al., 2011; Vizcarra et al., 2011; Zeth et al., 2011; Breitsprecher et al., 2012; Tu et al., 2012).

In addition to Bni1, budding yeast contains a second formin, Bnr1, which localizes to the bud neck (Kanei et al., 1998). Genetic evidence of bud6Δ defects in a bni1Δ background has suggested that Bud6 either directly or indirectly promotes Bnr1-mediated actin cable assembly, just as it does for Bni1, and indeed, Bud6 localizes to the bud neck in addition to sites of polarized growth (Tong et al., 2001; Delgehyr et al., 2008). However, the same purified fragment of Bud6 (residues 489–788) that stimulated Bni1 activity instead partially inhibited Bnr1 activity (Moseley and Goode, 2005). Thus, the interactions of Bud6–Bnr1, like Spire–Fmn2/Capu, have remained enigmatic. Together, these observations point to a deficit in our understanding of how formin collaborations are regulated and suggest that additional factors (absent in these in vitro assays) may be required for nucleation by such pairs.

Here, we addressed this issue by investigating the genetic and biochemical relationship between Bud6 and Bnr1. We uncovered a crucial difference in how Bud6 interacts with Bnr1 versus Bni1 and identified a regulatory sequence in Bud6 that specifically masks its NPF effects on Bnr1. Using proteomic approaches, we isolated a novel in vivo binding partner of Bud6, Bnl1, encoded by a previously uncharacterized gene. Bnl1 not only colocalized and cofunctioned with Bud6 to promote Bnr1-mediated actin cable assembly in vivo but bound directly to the regulatory region of Bud6 and unmasked Bud6 NPF effects on Bnr1 in vitro. Together, our results resolve the enigma of Bud6–Bnr1 activity and define a new ligand-activated mechanism for controlling collaborative actin assembly.

Results

Bud6 functions in vivo as an NPF for Bnr1

Bni1 and Bnr1 are the only two forms in Saccharomyces cerevisiae. Single deletions of either BN1 or BNR1 cause minimal defects in cell growth, but loss of both genes is lethal (Vallen et al., 2000; Ozaki-Kuroda et al., 2001). Bni1 and Bnr1 localize to the bud tip and bud neck, respectively, and from these positions promote the assembly of dynamic sets of actin cables that serve as tracks for myosin-dependent transport of secretory vesicles and other cargoes to the bud tip (Sagot et al., 2002a; Pruyne et al., 2004; Buttery et al., 2007).

To ask whether Bud6 functions in Bnr1-mediated cable assembly, we first generated an isogenic set of mutant strains (bni1Δ, bnr1Δ, bud6Δ, bud6Δbni1Δ, and bud6Δbnr1Δ) that were compared for cell growth and actin organization (Fig. 1). This analysis showed that bni1Δbud6Δ double mutants are more severely impaired for growth at 37°C compared with bni1Δ or bud6Δ single mutants (Fig. 1 A) in agreement with previous studies (Tong et al., 2001; Delgehyr et al., 2008). In addition, bni1Δbud6Δ double mutants showed increased numbers of cells with diminished cable staining, highly disorganized cables, and/or depolarized actin patches at 25°C (Fig. 1 C, quantification in D), confirming the results of Delgehyr et al. (2008) showing that Bud6 is required for proper Bnr1-dependent actin cable assembly and organization.

Next, we used specific NPF-impaired alleles of bud6Δ to test whether the requirement for Bud6 in stimulating Bnr1 in vivo stems from its NPF activities. Mutants separately impaired in binding to the formin tail (bud6Δ-35) and G-actin (bud6Δ-8) were integrated at the BUD6 locus in a bni1Δ background (Graziano et al., 2011). The resulting double mutants, bni1Δbud6Δ-35 and bni1Δbud6Δ-8, were compared with single mutants for cell growth and actin organization. bud6Δ-35 and bud6Δ-8 each caused strong defects in growth and actin organization in the bni1Δ background. Double mutants failed to grow at 37°C (Fig. 1 B), and >90% of double mutant cells at 25°C lacked visible cables (Fig. 1 C, and E, quantification). These results demonstrate that Bud6’s NPF activities are required in vivo for Bnr1-mediated actin cable assembly. In addition, we note that the bud6Δ-35 and bud6Δ-8 alleles showed slightly stronger defects in cell growth and actin organization than bud6Δ, which we previously determined is caused by recessive gain-of-function effects (Graziano et al., 2011).

The C terminus of Bud6 binds to Bnl1 and Bnr1 but only stimulates Bnl1 in vitro

To test whether Bud6 directly binds Bnr1, we used a construct, Bud6(L) (residues 489–788), which is the longest soluble fragment of Bud6 that we have been able to purify. Coomassie-stained gels of purified Bud6(L) and other key polypeptides used in this study are shown in Fig. S1. Bud6(L) was previously shown to...
Figure 2. Biochemical activities of purified Bud6(L) on yeast formins. (A) Domain layout of Bud6. Bud6(L) (residues 489–788) and Bud6(S) (residues 550–788) each contain the dimeric “core” domain (yellow; residues 550–688) that binds Bni1 and the “flank” domain that binds G-actin (blue; residues 689–788). Bud6(L) additionally contains a short N-terminal sequence of unknown function (red). (B and C) Quantitative binding assays using supernatant depletion analysis. The indicated concentrations of GST-Bud6(L) immobilized on glutathione beads were incubated with 1.0 µM C-Bni1 (B) or C-Bnr1 (C). For each data point, an equivalent reaction was performed using GST alone immobilized on an equal volume of glutathione beads to correct for nonspecific binding. Coomassie-stained gels below each plot show representative reactions for each of the datasets collected. Each band represents formin remaining in the supernatant after incubation with immobilized protein and glutathione agarose precipitation. The data in each panel were pooled from two independent experiments. In the top gel of C, intervening lanes were removed for presentation purposes (white line), but all bands are from the same gel. The lines in B and C are fits to the equation \( B = a \times c/(c + K) \), in which \( B \) is the fraction of C-Bni1 (B) or C-Bnr1 (C) bound, \( a \) is the amplitude of the binding interaction, \( c \) is the molar concentration of GST-Bud6(L), and \( K \) is the binding affinity (i.e., \( K_d \)). (D and E) 2 µM monomeric actin was polymerized in the presence of 10 nM C-Bni1 (D) or 2 nM Bnr1 (E), and the indicated concentrations of Bud6(L) in the absence (left) or presence (right) of 5 µM profilin. Data shown in each panel are from one representative example of four independent experiments. (F and G) Concentration-dependent effects of Bud6(L) on
bind C-Bni1 (FH1-FH2-C) and G-actin and to directly enhance C-Bni1 activity in a manner that depends on both interactions (Moseley et al., 2004; Moseley and Goode, 2005; Graziano et al., 2011). Recently, the crystal structure of a major portion of Bud6(L) was solved (residues 552–688), revealing a barrel-shaped antiparallel dimeric “core” domain that binds to the Bni1 tail region (Protein Data Bank accession nos. 3OKQ and 3ONX; Fig. 2 A, yellow bar; Tu et al., 2012). Furthermore, the flanking C-terminal sequence in Bud6 (residues 699–788) was shown to bind G-actin (Fig. 2 A, blue bar), whereas no function has been assigned to the remaining N-terminal sequences in Bud6(L) (resides 489–549; Fig. 2 A, red bar).

To test binding of Bud6 to Bnr1, we used supernatant depletions assays with variable concentrations of GST-Bud6(L) immobilized on glutathione agarose and a fixed concentration of soluble C-Bnr1. As a positive control for binding, we tested GST-Bud6(L) interactions with C-Bni1, and as a negative control, we tested binding to GST alone on beads. Our analysis revealed that GST-Bud6(L) binds specifically to C-Bni1 and C-Bnr1 with similar affinities ($K_d \approx 4–8 \mu M$; Fig. 2, B and C). In a previous study, we did not detect Bud6–Bnr1 interactions when monitoring bound material after multiple bead washes (Moseley and Goode, 2005), but the approach used here is a more reliable and quantitative one for detecting protein–protein interactions (Pollard, 2010). From these data, we conclude that Bud6 directly interacts with both Bnr1 and Bni1, which agrees with previous two-hybrid studies (Evangelista et al., 1997; Kikyo et al., 1999) and with our aforementioned genetic observations showing that Bud6 NPF activity contributes to Bnr1 function in vivo.

We next asked how Bud6(L) affects C-Bnr1 actin assembly activity, both in the presence and absence of profilin. As a positive control, we measured Bud6(L) effects on C-Bni1. As expected, Bud6(L) potently enhanced C-Bni1 activity in the presence or absence of profilin (Fig. 2 D), with a maximal sixfold increase in the rate of actin assembly (Fig. 2, F and G). In contrast, Bud6(L) failed to enhance C-Bnr1 activity in the presence of profilin (Fig. 2 E, quantification in F and G). Furthermore, in the absence of profilin, Bud6(L) inhibited C-Bnr1 in a concentration-dependent manner. These effects are likely caused by Bud6(L) binding C-Bnr1 rather than sequestering actin monomers, given that inhibition was observed at concentrations of actin monomers >10-fold higher than the concentration of Bud6(L).

Regulatory sequences in Bud6 “mask” its NPF effects on Bnr1
The discrepancy between our genetic data showing that Bud6 is an NPF for Bnr1 in vivo and our biochemical data showing that Bud6(L) inhibits rather than activates C-Bnr1 was puzzling and led us to consider whether Bud6 NPF effects on Bnr1 might be masked. The aforementioned structural study on Bud6 recently defined the boundaries of a dimeric “core” domain (550–688) and demonstrated that a truncated Bud6 construct, referred to here as Bud6(S) (residues 550–788), is sufficient to activate Bni1 in vitro (Fig. 2 A; Tu et al., 2012). Therefore, we tested the effects of Bud6(S) on Bnr1- and Bnr1-mediated actin assembly. Bud6(S) potently enhanced C-Bni1 activity in the absence of profilin (Fig. 3 A, left), similar to Bud6(L) (Fig. 2). Furthermore, the presence of profilin did not significantly alter the magnitude of the stimulatory effects at higher concentrations of Bud6(S) (Fig. 3 A, right), though it did decrease the potency of Bud6(S), presumably through competition for actin monomers (Fig. 3 B, $K_{app} \approx 11 \mu M$ without profilin and $K_{app} \approx 90 \mu M$ with profilin). Thus, Bud6(L) and Bud6(S) both increased by about sixfold the maximal rate of C-Bnr1–mediated actin assembly in the presence or absence of profilin (compare Fig. 2 [F and G] with Fig. 3 B).

Next, we tested the effects of Bud6(S) on C-Bnr1. In the presence of profilin, Bud6(S) potently stimulated C-Bnr1 (Fig. 3 C, right) with a $K_{app}$ of $\approx 30 \mu M$ (Fig. 3 D), whereas Bud6(L) failed to stimulate C-Bnr1 (Fig. 2 E–G). Interestingly, the ability of Bud6(S) to stimulate C-Bnr1 depended on the presence of profilin (Fig. 3 C, left), which differs from the profilin-independent stimulatory effects of Bud6(S) on C-Bni1 (see Discussion).

To better understand how Bud6(S) stimulates C-Bnr1, we compared binding of Bud6(S) to C-Bni1 ($K_d \approx 5.2 \mu M$) and C-Bnr1 ($K_d \approx 2.6 \mu M$; Fig. 3, E and F). Although profilin was required for the aforementioned stimulatory effects of Bud6(S) on C-Bnr1, the strength of the association between C-Bnr1 with Bud6(S) did not change appreciably when profilin, G-actin, or profilin and G-actin were present in the reactions (Fig. S2). Together with the data in Fig. 2 (B and C), these results show that although Bud6(S) and Bud6(L) bind to both formins with similar affinities, the presence of the additional N-terminal sequence in Bud6(L) (residues 489–549; from here on referred to as the regulatory region) “masks” the NPF effects on Bnr1 and does so without altering Bud6–Bnr1 affinity. Furthermore, we found that Bud6(S) and Bud6(L) each bind G-actin with affinities in the low nanomolar range (Fig. 3 G), suggesting that differences in actin monomer binding affinity do not explain differences in their NPF effects on C-Bnr1.

Bud6 stimulates actin nucleation rather than elongation by Bnr1
We previously used total internal reflection fluorescence (TIRF) microscopy (TIRF-M) to show that Bud6 enhances the actin nucleation rather than elongation activity of Bni1 (Graziano et al., 2011). The aforementioned observations prompted us to use TIRF-M to independently assess the effects of Bud6 on Bnr1-dependent actin filament nucleation versus elongation. First, we measured nucleation rates by quantifying filament density in reactions that had proceeded for a short time. Control reactions containing actin monomers and profilin produced a mean filament density of $14.8 \pm 2.0$ per $100 \mu m^2$ (Fig. 4 A, quantification in B). Addition of 0.2 nM C-Bnr1 increased filament density to
containing actin monomers and profilin, filaments elongated at a mean rate of 10.2 ± 0.3 subunits/s (Fig. 4 C, quantification in E). Addition of C-Bnr1 increased the elongation rate to 39.9 ± 1.2 subunits/s, and the combination of C-Bnr1 and Bud6(S) yielded filaments that elongated at a mean rate of 42.7 ± 1.5 subunits/s. Collectively, these results indicate that Bud6(S) dramatically increases the rate of Bnr1-dependent filament nucleation.

We next measured filament elongation rates by quantifying change in filament length over time. In control reactions containing actin monomers and profilin, filaments elongated at a mean rate of 10.2 ± 0.3 subunits/s (Fig. 4 C, quantification in E). Addition of C-Bnr1 increased the elongation rate to 39.9 ± 1.2 subunits/s, and the combination of C-Bnr1 and Bud6(S) yielded filaments that elongated at a mean rate of 42.7 ± 1.5 subunits/s. Collectively, these results indicate that Bud6(S) stimulates C-Bni1 and C-Bnr1 in actin assembly assays. (A and C) 2 µM monomeric actin was polymerized in the presence of 10 nM C-Bni1 (A) or 2 nM C-Bnr1 (C), and the indicated concentrations of Bud6(S) in the absence (left) or presence (right) of 5 µM profilin. Data shown in each panel are from one representative example of four independent experiments. (B and D) Concentration-dependent effects of Bud6(S) on C-Bni1 (B) or C-Bnr1 (D) actin assembly activity, performed as in A and C. Filled triangles indicate reactions performed in the presence of 5 µM yeast profilin; hollow triangles indicate identical reactions lacking yeast profilin. Data shown are from one representative example of four independent experiments. See Materials and methods for calculation of rates. Both lines in B and the solid line in D are fits to the equation $B = a \times c/(c + K)$, in which $B$ is the percent increase in formin activity, $c$ is the molar concentration of Bud6(S), $a$ is the percent increase in formin activity at saturating concentrations of Bud6(S), and $K$ is the concentration of Bud6(S) at which $B = 0.5 \times a$ (i.e., the $K_{app}$). The dashed line in D is drawn to guide the eyes. (E and F) Quantitative GST pull-down assays performed as in Fig. 2 (B and C) using indicated concentrations of immobilized GST-Bud6(S) and 1.0 µM of soluble C-Bni1 (E) or C-Bnr1 (F). The data in each panel were pooled from two independent experiments. The lines in E and F are fits to the equation $B = a \times c/(c + K)$, in which $B$ is the fraction of C-Bni1 (E) or C-Bnr1 (F) bound, $a$ is the amplitude of the binding interaction, $c$ is the molar concentration of GST-Bud6(S), and $K$ is the binding affinity (i.e., $K_d$). (G) Quantitative binding assays using 150 nM pyrene-labeled actin (100% labeling efficiency) and indicated amounts of either Bud6(L) or Bud6(S). The lines in G are fits to the equation $B = \frac{[c + a + k] - \sqrt{[c + a + k]^2 - 4 \times c \times a}}{2 \times a}$, in which $B$ is the fraction of G-actin bound, $c$ is the molar concentration of Bud6, $a$ is the molar concentration of G-actin (170 nM in all cases), and $k$ is the binding affinity (i.e., $K_d$). AU, arbitrary unit.
Bud6(S) strongly enhances Brn1’s nucleation but not elongation activity, demonstrating the Bud6 is by definition an NPF for both formins.

Other NPFs, including Wiskott–Aldrich syndrome protein, APC, and Bud6 itself (when acting on Bni1), function by recruiting actin monomers to the nucleator. We therefore tested
We asked whether the tail region of Bnr1 similarly mediates Bud6 binding. In supernatant depletion assays, C-Bni1\(\Delta\)tail failed to bind either GST-Bud6(L) or GST-Bud6(S) (Fig. 5 A, left), consistent with the position of the BBS in the Bni1 tail region. In contrast, C-Bnr1\(\Delta\)tail bound to both GST-Bud6(L) and GST-Bud6(S) and with only slightly reduced affinity to C-Bnr1 (Fig. 5 A, right; compare with Fig. 2 C and Fig. 3 F). Thus, the tail region of Bnr1 is not essential for Bud6 binding. Consistent with this view, Bud6(L) inhibited C-Bnr1\(\Delta\)tail activity (Fig. 5 B, left). Furthermore, we found that Bnr1 FH2 alone (lacking FH1 or tail but including the long \(\alpha\)T helix leading up to the DAD; Xu et al., 2004) bound to GST-Bud6(S) with a similar affinity to C-Bnr1\(\Delta\)tail (Fig. 5 C). Together, these results indicate that the primary BBS in Bnr1 is located outside of the tail region (see Discussion).

Interestingly, we also observed that although Bud6(S) binds to C-Bnr1\(\Delta\)tail, it fails to enhance C-Bnr1\(\Delta\)tail activity (Fig. 5 B). Thus, formin binding by Bud6 is not sufficient to confer its NPF effects, and the tail region also plays a pivotal role in this process.

The location of the Bud6 binding site (BBS) is different in Bnr1 and Bni1

Distinct effects of Bud6(L) on Bni1 versus Bnr1 (Fig. 2, D–G) prompted us to ask whether Bud6 binds to the same or distinct regions of each formin. Our previous work showed that the tail region of Bni1 contains the BBS, which is marked by tandem serines and a cluster of positively charged residues located on the C-terminal side of the DAD domain (Moseley and Goode, 2005). We asked whether the tail region of Bnr1 similarly mediates Bud6 binding.

In supernatant depletion assays, C-Bni1\(\Delta\)tail failed to bind either GST-Bud6(L) or GST-Bud6(S) (Fig. 5 A, left), consistent with the position of the BBS in the Bni1 tail region. In contrast, C-Bnr1\(\Delta\)tail bound to both GST-Bud6(L) and GST-Bud6(S) and with only slightly reduced affinity to C-Bnr1 (Fig. 5 A, right; compare with Fig. 2 C and Fig. 3 F). Thus, the tail region of Bnr1 is not essential for Bud6 binding. Consistent with this view, Bud6(L) inhibited C-Bnr1\(\Delta\)tail activity (Fig. 5 B, left). Furthermore, we found that Bnr1 FH2 alone (lacking FH1 or tail but including the long \(\alpha\)T helix leading up to the DAD; Xu et al., 2004) bound to GST-Bud6(S) with a similar affinity to C-Bnr1\(\Delta\)tail (Fig. 5 C). Together, these results indicate that the primary BBS in Bnr1 is located outside of the tail region (see Discussion).

Interestingly, we also observed that although Bud6(S) binds to C-Bnr1\(\Delta\)tail, it fails to enhance C-Bnr1\(\Delta\)tail activity (Fig. 5 B). Thus, formin binding by Bud6 is not sufficient to confer its NPF effects, and the tail region also plays a pivotal role in this process.
Isolation of a novel Bud6-binding protein that activates NPF effects on Bnr1

Given the aforementioned observations, we hypothesized that additional binding partners of Bud6 may be required to unmask its NPF effects on Bnr1 in vivo. To address this, we integrated a C-terminal GFP tag on *BUD6*, immunoprecipitated Bud6-GFP from cell extracts, and identified Bud6-associated proteins by tandem mass spectrometry analysis (see Materials and methods). One protein, encoded by the gene *YOR304C-A*, was selected for further analysis because it had previously been identified in proteomic studies as localizing to polarity sites and interacting with Bud6 (Huh et al., 2003; Krogan et al., 2006; Yu et al., 2008; Narayanaswamy et al., 2009). *YOR304C-A* encodes a protein that is only 76 amino acids long, and we refer to it as Bil1 (Bud6-interacting ligand).

Bil1 was expressed and purified in *Escherichia coli* as a GST fusion protein and tested for its ability to bind Bud6(S) and Bud6(L). GST-Bil1 bound to Bud6(L) but not Bud6(S) (Fig. 6 A), indicating that the regulatory region is essential for Bil1 binding. Next, we tested Bil1 (GST tag removed) in the presence of Bud6(L) or Bud6(S) for effects on Bnr1-mediated actin assembly. Bil1 showed no effects on actin assembly in the absence of other factors (Fig. S3 A) and no effects on Bnr1-mediated actin assembly in the absence of Bud6 (Fig. S3 B). However, in the presence of Bud6(L), Bil1 caused a concentration-dependent increase in the rate of C-Bnr1–mediated actin assembly (Fig. 6 B, quantification in C). In contrast, Bil1 showed no effects on C-Bnr1 in the presence of Bud6(S) (Fig. S3 C and quantification in F). TRIF-M analysis confirmed that Bil1 increased the number of filaments nucleated by C-Bnr1 in the presence of Bud6(L) (Fig. 6 D, quantification in E), while showing minimal effects on rate of filament elongation (Fig. 6 F).

Using all of the aforementioned observations, we constructed a working model for the differential regulation of Bni1 and Bnr1 by Bud6 (Fig. 6, G and H). A key feature of this model is that the location of the BBS (Fig. 6, G and H, red boxes) is different in Bni1 and Bnr1, such that it is farther from the FH2 domain in Bni1. The BBS interacts with a recently defined formin binding site (Fig. 6, G and H, dotted red circles) on the dimeric Bud6<sup>core</sup> domain (Tu et al., 2012). The R (regulatory) region of Bud6(L) is much closer to the FH2 domain in Bnr1 versus Bni1. We propose that the proximity of the R region to the FH2 domain obstructs nucleation, explaining why Bud6(L) stimulates Bni1 in the absence of additional factors (Fig. 6 G) but can stimulate Bnr1 only after addition of Bil1, which binds to and neutralizes the R region (Fig. 6 H).

**Bil1 colocalizes with Bud6 and functions in the Bnr1 pathway for actin assembly**

To investigate the in vivo functions of Bil1, we first generated strains in which we separately integrated C-terminal GFP tag on *BIL1* and *BUD6* and compared localization patterns at different stages of bud growth (Fig. 7 A and Fig. S4). Bud6-GFP primarily localized to the bud tip of small-budded cells and then progressively shifted to the bud neck as the daughter cell increased in size (Fig. S4, top), consistent with previous studies (Jin and Amberg, 2000; Segal et al., 2000). Bil1-GFP showed a similar pattern of localization to Bud6-GFP at all stages of bud development (Fig. S4, bottom), although Bil1-GFP fluorescence intensity was noticeably lower than Bud6-GFP, which agrees with previous quantitation of Bud6-GFP and Bil1-GFP levels in cells (Huh et al., 2003). In addition, we examined Bil1-GFP localization in bud6<sup>Δ</sup> cells, and Bud6-GFP localization in biliΔ cells. This revealed that Bil1-GFP shifts to the cytosol in bud6<sup>Δ</sup> cells (Fig. 7 A, bottom), whereas Bud6-GFP localization is unaffected by biliΔ (Fig. 7 A, top). Thus, Bil1 colocalizes with Bud6 and depends on Bud6 for localization, whereas Bud6 localization is not dependent on Bil1. We also generated a strain with integrated Bil1-GFP and Bud6-RFP to compare localization in the same cells (Fig. 7 B). Bil1-GFP and Bud6-RFP again were enriched at the bud neck and bud cortex and displayed colocalization at the neck (Fig. 7 B, arrows). Each protein was also visible as less bright spots in the mother and bud. However, we were unable to determine the degree to which these secondary spots colocalized because they were highly dynamic as previously reported for Bud6-RFP (Buttery et al., 2007) and many of them moved faster than the two-color acquisition rate.

Finally, to investigate the importance of Bil1 in the Bni1- and Bnr1-dependent pathways for actin cable assembly, we generated a biliΔ mutation and compared its effects on cell growth in wild-type, bni1Δ, and bnr1Δ backgrounds (Fig. 7 C). biliΔ caused no obvious defects in growth in the wild-type or bnr1Δ backgrounds but strongly impaired cell growth at 37°C in the bni1Δ background, similar to bud6Δ (Fig. 7 C). Furthermore, biliΔ exacerbated actin organization defects in the bni1Δ but not the bnr1Δ background, increasing the numbers of cells with diminished cable staining, highly disorganized cables, and/or depolarized actin patches (Fig. 7, D and E, quantification). We also generated a triple mutant bni1Δbud6ΔbiliΔ strain, which displayed defects in cell growth and actin organization similar to the bni1Δbud6Δ strain (Fig. S4). These results suggest that BILI and BUD6 function in the same pathway regulating BNR1.

To additionally test cable function in mutant strains, we tracked the movements of secretory vesicles (marked with GFP-Sec4), which are trafficked by the type V myosin Myo2 on actin cables. For each strain, we scored the percentage of anterograde movements (toward the bud tip) versus random and/or retrograde movements (Fig. 7 F and Videos 1–6). Consistent with our actin staining results, bni1Δbud6Δ and bni1ΔbiliΔ mutants exhibited a higher percentage of random and/or retrograde vesicle movements (84% and 87%, respectively) compared with wild-type cells (31%) or compared with single mutant bni1Δ, bud6Δ, and biliΔ cells (64, 61, and 65%, respectively). Although biliΔ cells displayed no clear defects in cable organization by actin staining, they did show defects in secretory vesicle movement, suggesting that biliΔ may alter the architecture of actin cables in a manner that is not readily detected by light microscopy. Collectively with our biochemical data, these in vivo results provide strong support for the model that Bil1 promotes Bnr1-dependent actin cable assembly.

**Discussion**

In this work, we set out to answer the long-standing question of whether Bud6 directly regulates Bnr1 activity. Early genetic
Figure 6. Bil1 unmasks Bud6(L) stimulatory effects on Bnr1. (A) Quantitative GST pull-down assays using indicated concentrations of purified immobilized GST-Bil1 and soluble Bud6(L) or soluble Bud6(S). Data shown were pooled from three independent experiments. The line in A is a fit to the equation B = a × c/(c + K), in which B is the fraction of Bud6 bound, a is the amplitude of the binding interaction, c is the molar concentration of GST-Bil1, and K is the binding affinity (i.e., $K_d$). (B) Bulk actin assembly assays. 2 µM monomeric actin was assembled in the presence of 5 µM yeast profilin and 2 nM C-Bnr1. Where indicated, 100 nM Bud6(L) and/or 500 nM Bil1 was included. The data shown are one representative example of four independent experiments. (C) Concentration-dependent effects of Bil1 on Bnr1-mediated actin assembly in the presence of either Bud6(L) or Bud6(S). Data shown were pooled from four independent experiments. The line in C is a fit to the equation $B = a \times c/(c + K)$, in which B is the percent increase in actin assembly, a is the percent increase in actin assembly at saturating concentrations of Bil1, and K is the concentration of Bil1 at
studies and two-hybrid experiments pointed to a role for Bud6 in promoting Bnr1-dependent actin cable assembly either directly or indirectly (Amberg et al., 1997; Kikyo et al., 1999; Delgehyr et al., 2008). However, a subsequent biochemical study using purified Bud6(L) (residues 489–788) showed that Bud6(L) stimulated Bni1 but not Bnr1-dependent actin assembly (Moseley and Goode, 2005). These results left it unclear whether Bud6 directly regulates Bnr1 function. We investigated this issue by taking a combined genetic and biochemical approach. Integrated bud6 alleles that are specifically defective in formin binding (bud6-35) and G-actin binding (bud6-5) caused growth defects and further reduced levels of actin cable staining in a bnl1Δ background, where Bnr1 is the only formin expressed. These data demonstrate that Bud6 directly promotes Bnr1-mediated actin cable assembly because all cables in these cells are generated by Bnr1. Furthermore, we found that purified Bud6(L) binds to both Bnr1 and Bni1 with similar affinity. However, although Bud6(L) enhanced nucleation by Bni1 in vitro, it partially inhibited Bnr1, making it unclear how Bud6 could stimulate Bnr1 in vivo. Analysis with a shorter construct, Bud6(S), resolved this issue, as we observed that Bud6(S) stimulated both Bni1 and Bnr1 activity. These observations suggested that Bud6 stimulation of Bnr1 might require additional cellular factors. Using affinity-tagged endogenously expressed Bud6, we isolated from cell extracts a novel Bud6-binding partner, Bil1, which we showed binds to a regulatory sequence in Bud6 (residues 489–549) and unmasks Bud6(L) NPF effects on Bnr1. Bil1 also colocalized with Bud6 at the bud neck, where Bnr1 resides, and depended on Bud6 for its localization, consistent with their direct interaction. Finally, genetic analysis demonstrated that Bil1 functions in the Bnr1-dependent pathway of cable assembly and, consequently, that bil1Δ causes defects in the movements of secretory vesicles.

These findings have several broad implications. First, they resolve earlier discrepancies between genetic and biochemical data on Bud6–Bnr1 interactions, demonstrating that Bud6 directly binds and stimulates Bnr1 and that Bud6–Bnr1 interactions are important for actin cable assembly and function in vivo. Second, they reveal an unanticipated “ligand-gated” mechanism for activating this NPF–formin collaboration in actin nucleation, which may serve as a paradigm for understanding the regulation of other formin collaborations. Third, they show that two different formins expressed in the same cell type can be stimulated by a single NPF through distinct regulatory mechanisms and that this may be achieved simply by shifting the location of the NPF binding site on the formin.

Mechanism of ligand-induced activation of Bud6–Bnr1

We found that Bud6(L) and Bud6(S) each bind to Bni1 and Bnr1 with similar affinities. However, Bud6(L) only stimulated Bni1 activity, whereas Bud6(S) stimulated both Bni1 and Bnr1. These observations suggested that the sequence by which Bud6(L) and Bud6(S) differ (489–549) masks the NPF effects of Bud6 on Bnr1 but not Bni1.

How is differential regulation of two formins by the same NPF achieved? An important clue is that the same point mutations (bud6-35), located in the dimeric core domain of Bud6, abolish interactions with both Bni1 (Graziano et al., 2011) and Bnr1 (Fig. 4F). This suggests that Bud6 binds to each formin through interactions of a similar molecular nature. A second clue is that the position of the BBS is different in Bnr1 compared with Bni1. Our data show that Bud6 binds to C-Bni1 but not C-Bnr1 Δtail, indicating that the BBS is contained in the tail region of Bni1, consistent with previous mapping (Moseley and Goode, 2005). In contrast, Bud6 bound with similar affinities to C-Bnr1, C-Bnr1 Δtail, and Bnr1 FH2, demonstrating that the BBS in Bnr1 is contained in the FH2 region. This construct consists of the donut-shaped dimeric FH2 domain plus two long αT helices that extend away from its surface and connect to the C-terminal DAD-containing tail region (Fig. 6, G and H; Xu et al., 2004). Although the exact position of the BBS in Bnr1 has yet to be determined, it is notable that the tandem serine residues found in Bni1 that are just C-terminal to its DAD domain and critical for Bud6 binding are not conserved in Bnr1 (Moseley and Goode, 2005). However, tandem serines followed by a cluster of positively charged residues instead appear along the αT helix of Bnr1, i.e., substantially closer to the main body of the FH2 domain. Binding of Bud6 to that site would put the Bud6 regulatory region (489–549) in a better position to obstruct nucleation by the FH2 domain (in the absence of Bil1), perhaps by inhibiting FH2 dimer capture of actin seeds. Thus, a shift in the position of the BBS could explain how two formins can be differentially regulated by one NPF and explain why ligand-gated activation is required for one Bud6–formin pair but not the other (Fig. 6, G and H, model). Consistent with this model, we have previously shown that fusing the BBS-containing tail region of Bni1 onto the FH1-FH2-αT of Bnr1 enables Bud6(L) to stimulate Bnr1 (Moseley and Goode, 2005). This chimera should have two BBS elements, the distal one being far enough from the FH2 domain to allow Bud6(L) to provide the observed NPF effects on the chimera.

One other difference we noted between the NPF effects of Bud6 on Bni1 versus Bnr1 was that profilin was required...
Figure 7. Analysis of Bil1 localization and function in vivo. (A) Comparisons of Bud6-GFP localization in wild-type and bil1Δ cells (top), and Bil1-GFP localization in wild-type and bud6Δ cells (bottom). Bar, 10 µm. (B) Representative images of Bil1-GFP and Bud6-RFP localization in the same cells. Strong overlapping signals were observed at the bud neck (cyan arrowheads). Bar, 10 µm. (C) 10-fold serial dilutions of the indicated strains grown on YEPD on May 2, 2017. (D) Representative images of Bil1-GFP localization in wild-type and bil1Δ cells. (E) Graph showing the percentage of budded cells at 25°C and 37°C. (F) Graph showing the percentage of vesicle movements in anterograde and random/retrograde directions.
specifically for Bud6 NPF effects on Bnr1 and not Bni1. We do not yet understand the basis for this mechanistic difference between Bnr1 and Bni1. However, previous studies have shown that the FH1 domains in some formins contribute to actin nucleation specifically in the presence of profilin (Li and Higgs, 2003; Paul and Pollard, 2008; Gould et al., 2011). Thus, it is possible that FH1–profilin–actin complexes could deliver actin monomers to Bud6 or work in parallel with Bud6 to recruit monomers for Bnr1-dependent nucleation.

**Bil1 in vivo functions**

What in vivo function is served by Bil1 regulation of Bud6 effects on Bnr1? One possibility is that Bil1 functions as a molecular “thermostat,” which can define the fraction of Bud6 (from the cellular pool) available for productive nucleation interactions with Bnr1. In support of this view, Bil1 levels are significantly lower (approximately fourfold) than Bud6 throughout bud development (Huh et al., 2003). Thus, Bil1 may restrict levels of cable assembly by Bud6–Bnr1 (a powerful nucleation unit), scaling them to Bil1 levels, while not affecting the pool of Bud6 that is available to stimulate Bnr1. Such a thermostat mechanism would permit cells to alter Bud6 levels for the purpose of controlling Bnl1-dependent cable assembly without overstimulating Bnr1, and indeed, Bud6 levels fluctuate in a cell cycle–regulated manner (Moseley and Goode, 2005).

A second possibility is that Bil1 links Bud6–Bnr1 activation to upstream regulatory pathways, enabling a cable assembly response to signals controlling membrane trafficking, organelle inheritance, cell cycle stage, bud size, or response to environmental stress. Bni1 and Bnr1 nucleate actin assembly from two distinct sites and produce separate sets of cables with different elongation speeds (Yu et al., 2011). Small proteins, such as Bil1 (8.6 kD), can be translated rapidly in response to cues, and thus, Bil1 production/degradation may provide a rapid way to tune Bnr1 function (Bnr1 itself is 156.8 kD, and therefore, its up-regulation would be much slower). Thus, a mechanism involving Bil1 could allow the two formins to more readily adapt to environmental stresses, such as cell wall damage, which was recently shown to trigger recruitment of Bnr1 to the cortical wound site (Kono et al., 2012).

**Relationship between Bud6 and other formin NPFs**

Our results lend new insights into how collaborative nucleator pairs in other systems may be regulated. Although the three known formin-interacting nucleators/NPFs (Bud6, Spire, and APC) share little if any sequence homology, they appear to have related mechanisms and functions. Each binds to the C-terminal region of the formin and to multiple actin monomers and is thought to catalyze the formation of an actin seed, which is then captured at its barbed end by the FH2 domain. In addition, Bud6, Spire, and APC each are reported to bind microtubules and regulate microtubule-dependent processes in vivo, and Bud6 and APC interact with the microtubule plus end-tracking protein EB1 (Su et al., 1995; Kita et al., 2006; Rosales-Nieves et al., 2006; Delgehyr et al., 2008; Ten Hoopen et al., 2012). Thus, actin- and microtubule-based roles for these NPFs and the formins they bind are rapidly being defined. However, by comparison, relatively little is known about how NPF–formin interactions are regulated in vivo. Our results suggest that these collaborative associations may remain idle until activated by specific ligands. This paradigm may also be relevant to understanding Spire–formin interactions. Genetic data indicate that Spire cooperates with the formin Capu/Fmn2 to generate cytoplasmic actin networks in both Drosophila and mouse oocytes (Pfender et al., 2011; Schuh, 2011). However, purified Spire partially inhibits rather than enhances Capu/Fmn2 activity in vitro (Quinlan et al., 2007; Vizzcarra et al., 2011). This paradox resembles the one that surrounded Bud6 and Bnr1 at the onset of this study, raising the possibility that even though Spire binds to the formin, it contains regulatory sequences obstructing its NPF effects, which must be released by binding of a specific ligand and/or posttranslational modification.

**Materials and methods**

**Plasmids and strains**

Vectors previously described (Moseley et al., 2004; Moseley and Goode, 2005; Tu et al., 2012) were used for galactose-inducible expression in S. cerevisiae of N-terminal His4, fusions of C-Bnl1 (residues 1,227–1,953), C-Bnr1 (residues 1,227–1,797), C-Bnr1 (residues 757–1,375), and C-Bnr1 (residues 757–1,292) for E. coli expression of GST-tobacco etch virus (TEV)-Bud6(L) (residues 478–788) and GST-TEV-Bud6(S) (residues 550–788). The E. coli expression vector for Bnr1 FH2 domain was a gift from M. Rosen (Howard Hughes Medical Institute, University of Texas, Southwestern Medical Center at Dallas, Dallas, TX). To construct vectors for E. coli expression of GST-TEV-Bud6-35(S) and GST-TEV-Bud6-8(S), we PCR amplified sequences encoding residues 550–788 from vectors expressing GST-TEV-Bud6-35(S) and GST-TEV-Bud6-8(S). We isolated and subcloned these into the pET-H and Nol sites of pET-GST-TVE (Moseley et al., 2004) to produce pBG1363 and pBG1364, respectively (Graziano et al., 2011) and subcloned these into the BamHI and Nol sites of pET-GST-TVE (Moseley et al., 2004) to produce pBG1363 and pBG1364. A plasmid for expressing Bil1 in E. coli (pBG1367) was generated by PCR amplifying the BIL1 ORF from the wild-type yeast strain BGY12 and subcloning this fragment into the BamHI and Nol sites of pET-GST-TVE.

All yeast strains used in this study were isogenic to BGY12 (MATα; his3-11,15; ura3-52; leu2-3,112; ade2-1; trp1-1; his3-11,15; trp1-1; psr+; sso; Galh; ORF from E. coli; his3-11,15; ura3-52; leu2-3,112; ade2-1; trp1-1; psr+; ORF from E. coli) or BGY10 (MAA; his3-11,15; ura3-52; leu2-3,112; ade2-1; trp1-1; psr+; Galh; ORF from E. coli) unless otherwise noted. Strains bnl1Δ (BGY1247), bnr1Δ (BGY1248), bud6Δ (BGY1413), bud6Δ-35 (BGY1411), and bud6Δ-8 (BGY1412) were generated in previous studies (Chesarone et al., 2009; Graziano et al., 2011). We generated bnl1Δbud6Δ-35 (BGY1476) and bnl1Δbud6Δ-8 (BGY1477) by crossing BGY1411 and BGY1412 to BGY1247 followed by sporulation and tetrad dissection. Similarly, bnl1Δbud6Δ-35 (BGY1478) and bnl1Δbud6Δ (BGY1479) were generated by crossing BGY1412 to plates at either 25 or 37°C. (D) Representative images of F-actin staining for the indicated strains. Bar, 5 µm. (E) Quantification of actin cable phenotypes (same categories as in Fig. 1, D and E). Note that data for some of the strains that appear in Fig. 1 D again appear here to facilitate comparison of phenotypes among relevant strains. The data for all of these strains were collected in the same sets of experiments. For each strain, >200 cells were scored (approximately equal numbers of cells pooled from two independent experiments). (F) Tracking of GFP::Sec4 particles in cells. Moving particles were followed over a 60 s observation window and placed into one of two categories: (1) normal anterograde movements (particles moving directionally toward the bud) or (2) random/retrorgade movements. For each different yeast strain, two to three individual particles were tracked in 50 cells (n > 140 particles total, from approximately equal numbers of cells imaged in two independent experiments).
BVG1247 and BVGY1248, respectively. The bil1 strain (BVGY1480) was generated by homologous recombination using a HIS3MX6 cassette (Longtine et al., 1998). To generate bud3ΔΔbil1 strain (BVGY1481), bni1ΔΔbil1 strain (BVGY1482), and bnr1ΔΔbil1 strain (BVGY1489) strains, BVGY1480 was crossed to BVGY1413, BVGY1247, and BVGY1248, respectively. To generate bud3ΔΔbil1ΔΔbni1 strain (BVGY1489), bil1 strain was deleted as described for BVGY1480 in BVGY1478. Bud6-GFP (BVGY1484) or Bil1-GFP (BVGY1485) strains were generated by recombination using a Gateway System (Invitrogen). The F-actin stain TRITON X-100 (1% 1 mg) and the 6His-fusion proteins were gel filtered on a Superose 12 (GE Healthcare) equilibrated in buffer HEKG10D (20 mM Tris-HCl, pH 8.0, 50 mM NaCl, 1% (vol/vol) Triton X-100, 1 mM DTT, and standard protease inhibitors).

C-Bnr1 (residues 1,227–1,953), C-Bnr1 (residues 757–1,375), C-Bil1 (residues 1,292–1,957), and C-Bil1 (residues 1,1–1,292) were expressed in E. coli as previously described (Moseley et al., 2006). For each formin polypeptide, 2–4 liters of yeast cells were grown in synthetic medium lacking uracil and 2% raffinose to OD600 = 0.6–0.9, and then, protein expression was induced by the addition of 2 mM 3-amino-1,5-dimethyl-2,4-imidazolidinedione (3-AMT) and 2 mM glycerol. The resulting protein was stored at −80°C until use. Purification of C-Bnr1 and C-Bil1 was performed as described (Gould et al., 2011; Graziano et al., 2011). In brief, frozen yeast lysate was resuspended in buffer A (20 mM NaPO4, pH 7.4, 150 mM NaCl, 0.5 mM DTT, 1% NP-40, and standard protease inhibitors) and then cleared by ultracentrifugation at 80,000 rpm for 20 min in a rotor (TLA-100.3). The supernatant was incubated with Ni-nitrilotriacetic acid (NiTA) beads for 1.5 h at 4°C, and then, the beads were washed with buffer B (no protease inhibitors or NP-40), and proteins were eluted with buffer A + 300 mM imidazole. Purified fusion protein was loaded onto a column (Superox 12; GE Healthcare) equilibrated in buffer HEKG10D (20 mM Hepes, pH 7.5, 1 mM EDTA, 50 mM KCl, 10% (vol/vol) glycerol, and 1 mM DTT), and peak fractions were pooled, aliquoted, snap frozen, and stored at −80°C. C-Bnr1 and C-Bil1 were purified similarly, except that the cleared yeast lysates were filtered through a 0.45-µm syringe-driven filter unit (Millipore; EMD Millipore), and the 6His-fusion proteins were isolated on a purification system (Profinia; Bio-Rad Laboratories) using the native IMAC (immobilized metal ion affinity chromatography) + desalting program (1-ml IMAC column + 5-ml desalting column). The desalting buffer used was HEKG10D. The eluted C-Bnr1 and C-Bil1 (4 ml) were concentrated using centrifugal filter units (molecular mass cutoff of 30 kD; Amicon Ultra; EMD Millipore) to a final volume of ~0.7 ml. C-Bnr1 and C-Bil1 were dialyzed against buffer C (buffer B + 0.4 M KCl) overnight at 18°C. The resulting peak fraction was loaded onto a column (HiTrap Q; GE Healthcare) and eluted with a 15-ml salt gradient (0–400 mM NaCl) in 20 mM Tris-HCl, pH 8.0. Peak fractions were pooled, concentrated to 5 ml, and then loaded onto a gel filtration column (26/60 Superdex 75; GE Healthcare). Again, peak fractions were pooled, snap frozen in liquid N2, and stored at −80°C.

Actin assembly assays

Before each experiment, gel-filtered monomeric actin in G buffer was cleared by ultracentrifugation for 1 h at 4°C at 90,000 rpm in a rotor (TLA-100), and the top ~75% of the supernatant was carefully removed. Actin assembly reactions (60 µl) contained 2 mM G-actin (5% pyrene labeled) and 5 µM yeast profilin where indicated. G-actin was converted to Mg2+-ATP-actin 2 min before use, and then, 42 µl G-actin was mixed rapidly with 15 µl proteins/control buffer followed by 3 µl of 20x initiation mix (40 mM MgCl2, 10 mM ATP, and 1 mM KCl) before the start of reactions. Pyrene-actin fluorescence was monitored in a plate reader (Infinite M200; Tecan) at room temperature and emissions at 360 and 460 nm, respectively. Kapp corresponds to the concentration of Bud6 or Bnr1 [in the presence of Bud6] required for half-maximal stimulation of formin-mediated actin assembly and was determined by first measuring the slopes of the polymerization curves for the initial 200 s of each reaction and then dividing the slopes of the reactions containing the variable component (e.g., Bud6) by the slopes of the reactions lacking the component. The resulting "normalized" rates were plotted as a function of the concentration of the
variable component. For all assembly assays, at least two independent experiments were performed using different stocks of purified proteins. The data shown in Fig. 3 G are representative results from one of the individual experiments.

Quantitative supernatent depletion pull-down assays

During purification of GST-Bud6 constructs from E. coli (Graziano et al., 2011), the amount of GST-Bud6 bound to beads was quantified by SDS-PAGE and Coomassie staining. Then, variable concentrations of immobilized GST-Bud6 were incubated for 10–15 min at room temperature with a fixed concentration of soluble formin (1–2 μM). All reactions were performed in HEND (20 mM Hepes, pH 7.5, 1 mM EDTA, 100 mM NaCl, and 1 mM DTT). Beads were pelleted, and supernatants were recovered. The amount of formin remaining in the supernatant of each reaction was determined by SDS-PAGE and Coomassie staining and compared with the amount of formin remaining in the supernatants of control reactions containing beads with GST alone. This value was then used to calculate the amount of formin that had been bound by GST-Bud6. Quantification of Coomassie-stained bands was performed using an infrared imaging system (Odyssy; LI-COR Biosciences). The Kd for each Bud6–formin pair was calculated plotting the fraction of formin bound as a function of the concentration of Bud6 and fitting the data to a hyperbola (Pollard, 2010). All binding experiments were performed on a separate 2–3 d using different stocks of purified proteins.

Cell imaging

Fixation, staining, imaging, and analysis of yeast strains were performed as previously described (Graziano et al., 2011). In brief, yeast strains were grown to early/mid-log phase (OD600 0.3–0.5) in YEPD (yeast extract, peptone, and 2% glucose) supplemented with adenine, fixed in 4.5% formaldehyde for 45–60 min, and stained with Alexa Fluor 488-phalloidin (Life Technologies). Cells were imaged in mounting media (10 mM NaPO4, pH 7.4, 75 mM NaCl, 4.3 mM pheophytin, 0.01 mg/ml DAPI, and 45% glycerol [vol/vol]) at room temperature (25°C) using a microscope (Axioskop 2 mot plus; Carl Zeiss) equipped with a 100× Plan Apochromat objective, NA 1.40 (Carl Zeiss), and a digital charge-coupled device camera (ORCA-ER; Hamamatsu Photonics). All images of fixed cells were acquired using a chloroform–methanol–Acetone–water wash (6:6:2:2) for 5 min. Image analysis was performed as described for the imaging of fixed cells.

For two-color imaging of Bil1-GFP and Bud6-GFP strains, cells were grown in synthetic complete media + 2% glucose to early/mid-log phase and imaged in the same medium at room temperature. For single-color imaging (Fig. 7 A and F), 600-ms exposures were acquired with 2 × 2 binning; but otherwise, the same microscope configuration and analysis software was used as described for the imaging of fixed cells.

For two-color imaging of Bil1-GFP and Bud6-RFP (Fig. 7 B), cells were grown in synthetic complete media + 2% glucose to early/mid-log phase and imaged in the same medium at room temperature. Images were acquired using Elements AR software (Nikon) with laser excitation at 488 and 561 nm and a 100×, NA 1.45 Plan Apochromat objective on an upright microscope (NI-E; Nikon) equipped with a spinning-disk head (CSU-W1; Yokogawa Corporation of America), 525/40- and 617/73-nm emission filters, and an electron multiplying charge-coupled device camera (iXon 897U; Andor Technology). Image analysis was performed as described in the previous paragraph.

For live-cell imaging of GFP-sec4 particle movements, yeast strains carrying the GFP-sec4 plasmid (URA3 marked) were grown in synthetic media lacking uracil and 2% glucose to early/mid-log phase. Cells were then imaged in the same medium at room temperature on a spinning-disk confocal system (Marianas; 3I, Inc.), consisting of a microscope (Observer.Z1; Carl Zeiss) equipped with a 100× Plan Apochromat objective, NA 1.4, a spinning-disk confocal head (CSU-X1), and an electron multiplying charge-coupled device camera (QuantEM 512SC; Photometrics). Exposures of 150 ms were acquired every 200 ms over a time course of 60 s. Image acquisition and analysis were performed using SlideBook 5.0 (3I, Inc.) and ImageJ.

TIRF-M

Before all TIRF-M experiments, coverslips were coated with PEG-5000 and assembled into flow cells. Immediately before each experiment, flow cells were incubated for ~3 min in TBSA (Tris·HCl, pH 8.0, and 1% BSA) and then washed with TIRF buffer (10 mM imidazole, 50 mM KCl, 1 mM MgCl2, 1 mM EGTA, 0.2 mM ATP, 10 mM DTT, 1.5 mM glucose, 20 μg/ml glucose oxidase, and 0.5% methylcellulose [4,000 cp]) pH 7.4). Proteins in TIRF buffer were then mixed with 25 μM G-actin (10% Oregon green labeled) and added to the flow cell. Images for each reaction were acquired at 5-s intervals for a total of 600 s using an inverted microscope (Ti200; Nikon) with a 150-W argon laser (Mellot Griot), a 60× TIRF objective, NA 1.49 (Nikon), and an electron multiplying charge-coupled device camera (iXon; Andor Technology). Focus was maintained using the Perfect Focus System (Nikon). Temperature was maintained at 20–23°C. Elongation rates of filaments were determined by measuring the length of a single filament at 60 s intervals over a period of 300 s. Bnr1-elongated filaments were distinguished by their approximately fourfold faster elongation rate versus filaments elongating in the absence of formin. For each condition, three independent experiments were performed. To determine the number of filaments nucleated, each field of view was examined 450 s after G-actin was added to the reaction. For each condition, filament densities were calculated in a total of nine fields of view spanning three independent reactions. Analysis was performed using NIS Elements (Nikon) and ImageJ. All TIRF experiments were performed on a separate 2–3 d using different stocks of purified proteins. In Fig. 4 B and E and Fig. 6 E and F, the graphs show data averaged from two to three experiments. In Fig. 4 D, each line represents an individual actin filament taken from the same experiment.

Actin binding assays

Binding reactions were performed using 150 nM RMA (100% pyrene labeled), 600 nM latrunculin B, and varying concentrations of either Bud6(S) or Bud6(L). All reactions contained a final volume of 60 µl comprising 5 pl RMA in G buffer and 55 µl proteins in HK buffer (20 mM Hepes and 50 mM KCl). Upon reaching equilibrium, pyrene fluorescence was monitored as previously described (see subsection Actin assembly assays). Binding curves were generated by plotting Fluorescence/Fluorescenceeq (after subtracting the baseline pyrene fluorescence obtained from reactions containing no Bud6) as a function of Bud6 concentration. To determine the Ki for each reaction, data points from the plots were fitted using a quadratic equation (Pollard, 2010). Experiments were performed on two separate occasions using different stocks of purified proteins. The data shown in Fig. 3 G are representative results from one of the individual experiments.

Bud6-GFP pull-down and mass spectrometry analysis

Proteins were extracted by established protocols using GFP expressed and purified from E. coli (Cristea et al., 2005). A plasmid expressing 6His-GFP was transformed into E. coli strain BL21, cells were grown to log phase, and cells were induced at 25°C overnight using 1 mM IPTG. Cells were pelleted and stored at ~80°C. Pellets were thawed, resuspended in lysis buffer (PBS, pH 7.4, and standard protease inhibitors) and lysed by lysozyme treatment and sonication. Lysates were cleared by centrifugation at 12,000 rpm for 15 min at 4°C in a rotor (Sorvall S600), and then, ammonium sulfate was added to a final concentration of 50%, incubated on ice for 30 min, and centrifuged again (12,000 rpm for 15 min at 4°C). The soluble fraction of the ammonium sulfate cut was passed over a 5-ml Ni-NTA column three times. The Ni-NTA column was washed with lysis buffer (no protease inhibitors) and then, 6His-GFP was eluted using PBS + 300 mM imidazole, and the bound protein was further purified on a column equilibrated in PBS (26/60 Superdex 75). Peak fractions were pooled and concentrated. The purified 6His-GFP was injected into New Zealand white rabbits (Covance), and the bleeds were tested by Western blotting for specificity. Antibodies were then affinity purified for use in proteomic analyses (see following paragraph).

Large cultures of a yeast strain carrying an integrated GFP tag at the C terminus of Bud6 (BGY1484) and a control strain with no tag (BGY1257) were grown to late log phase, frozen, and lysed by mechanical perturbation under liquid nitrogen. Cell lysates from the two strains were clarified by ultracentrifugation and then incubated for 1 h with protein A beads coated with affinity purified α-GFP antibodies, which had been cross-linked to the beads using dimethyl pimelimidate (Sigma-Aldrich). Beads were then pelleted and washed, and the bound proteins were eluted with 0.5 M ammonium hydroxide and 0.5 mM EDTA. Samples were TCA precipitated, digested trypsin, and analyzed by tandem mass spectrometry and MudPIT (Multidimensional Protein Identification Technology). Among the proteins that associated specifically with Bud6-GFP, we focused on Yor304ca-a (Bil1) because it was uncharacterized and previously had been identified as a potential Bud6-binding partner in a proteome-wide tandem affinity purification–tagging study (Kroagen et al., 2006).

Online supplemental material

Fig. S1 shows Coomassie-stained SDS-PAGE gels of the key purified proteins used in this study; Fig. S2 shows quantitative GST pull-down assays performed as in Fig. 3 E and F using the indicated concentrations of
immobilized GST-Bud6(S) and 1.5 µM soluble CBn1. Fig. S3 shows bio-
chemical effects of Bil1 on actin assembly. Fig. S4 shows localization of
dependently expressed Bud6-GFP or Bil1-GFP throughout the cell cycle.
Fig. S5 shows genetic analysis of Bil1 function in a bni1Δbud6Δ strain.

We thank Tony Bretscher, David Pellman, and Mike Rosen for strains and plas-
mids. We thank John Yates and the Yeast Resource Center for performing the
mass spectrometry analysis and Ed Dougherty for assistance at the Brandeis
Corficial Imaging Laboratory. We are also grateful to David Pruyne, Avital
Rodal, Satoshi Yoshida, Denis Breitsprecher, Julian Eskin, and Casey Ydenberg
for helpful discussions and critical reading of the manuscript.

This work was supported by a grant from National Institutes of Health
[GM083187] to B.L. Goode.
