Abscission completes cytokinesis to form the two daughter cells. Although abscission could be organized from the inside out by the microtubule-based midbody or from the outside in by the contractile ring–derived midbody ring, it is assumed that midbody microtubules scaffold the abscission machinery. In this paper, we assess the contribution of midbody microtubules versus the midbody ring in the Caenorhabditis elegans embryo. We show that abscission occurs in two stages. First, the cytoplasm in the daughter cells becomes isolated, coincident with formation of the intercellular bridge; proper progression through this stage required the septins (a midbody ring component) but not the membrane-remodeling endosomal sorting complex required for transport (ESCRT) machinery. Second, the midbody and midbody ring are released into a specific daughter cell during the subsequent cell division; this stage required the septins and the ESCRT machinery. Surprisingly, midbody microtubules were dispensable for both stages. These results delineate distinct steps during abscission and highlight the central role of the midbody ring, rather than midbody microtubules, in their execution.

Introduction

Cytokinesis can be partitioned into two phases: (1) contractile ring constriction, which changes cell shape, and (2) abscission, which isolates the cytoplasm in the daughter cells and alters membrane topology to form two physically distinct cells. Contractile ring constriction is orchestrated by an array of antiparallel microtubule bundles called the central spindle and a cortical contractile ring that forms around the cell equator. As constriction nears completion, the central spindle and contractile ring mature to form the midbody and the midbody ring, which direct abscission (Fededa and Gerlich, 2012; Green et al., 2012; Agromayor and Martin-Serrano, 2013).

The midbody is a densely packed antiparallel microtubule array that sits in the center of the intercellular bridge (Glotzer, 2009; Green et al., 2012). The molecular composition of the midbody includes three key components also required to form the central spindle: (1) the microtubule cross-linking protein PRC1 (Glotzer, 2009; Walczak and Shaw, 2010), (2) the centralspindlin complex, consisting of the Mklp1 kinesin and the CYK4 Rho GAP (White and Glotzer, 2012), and (3) the chromosomal passenger complex containing the Aurora B kinase (Carmena et al., 2012). Whereas PRC1 and the chromosomal passenger complex remain associated with midbody microtubules (Hu et al., 2012), centralspindlin transitions in its localization from the midbody to the midbody ring (Elia et al., 2011; Hu et al., 2012).

The midbody ring, like the midbody, retains contractile ring components, including actin filaments, Myosin II, and septin filaments, as well as anillin and Citron kinase (Madaule et al., 1998; Gai et al., 2011; Hu et al., 2012; Kechad et al., 2012). The septins bind directly to the plasma membrane and are recruited to the contractile ring by Anillin (D’Avino, 2009; Piekny and Maddox, 2010; Oh and Bi, 2011; Mostowy and Cossart, 2012). In Drosophila melanogaster S2 cells, the Anillin N terminus, which binds actin and Myosin II, is important for midbody ring integrity, whereas the connection between the Anillin C terminus and the septins links the midbody ring to the plasma membrane (Kechad et al., 2012), a role similar to that proposed for the CYK4 C1 domain (Lekomtsev et al., 2012).
Figure 1. Abscission occurs in two stages: cytoplasmic isolation and release of the midbody/midbody ring. (A) Furrow diameter was measured in projections of the central region of z stacks of embryos (n = 10) expressing a GFP-tagged plasma membrane probe. (right) Graph plots mean furrow diameter versus time after furrow initiation. Arrow indicates the last time point when a hole can be detected (apparent closure). Error bars are the SDs. (top) Schematics illustrate shape changes during the first division in the C. elegans embryo, highlighting intercellular bridge structure. MTs, microtubules. (B, left)
Abscission could be organized from the outside in by the midbody ring or from the inside out by the midbody. Although the relative contributions of the midbody and midbody ring in scaffolding abscission have not been directly tested, the midbody is thought to serve as the platform that brings together the abscission machinery, including membrane trafficking components that narrow the intercellular bridge (Schiel and Prekeris, 2013) and the endosomal sorting complex required for transport (ESCRT) machinery, which executes the final scission event (Agromayor and Martin-Serrano, 2013; McCullough et al., 2013). In human cells, the ESCRT machinery is recruited by CEP55, which binds to centralspindlin late in cytokinesis; CEP55 binds Alix and ESCRT-I, which in turn recruit ESCRT-III proteins thought to polymerize to drive membrane scission (Fabbro et al., 2005; Zhao et al., 2006; Carlton and Martin-Serrano, 2007; Morita et al., 2007; Carlton et al., 2008; Lee et al., 2008; Bastos and Barr, 2010; Elia et al., 2011; Guizetti et al., 2011).

The point when the cytoplasm in the daughter cells becomes isolated from each other (hereafter termed cytoplasmic isolation) has been monitored by following the diffusion of fluorescent probes (Lo and Gilula, 1979; Sanger et al., 1985; Steigemann et al., 2009; Guizetti et al., 2011). In HeLa cells, cytoplasmic exchange ceases ~60 min after the completion of furrowing, coincident with ESCRT-III–mediated scission (Steigemann et al., 2009; Guizetti et al., 2011).

Here, we analyze abscission in the early Caenorhabditis elegans embryo. We show that abscission occurs in two stages: cytoplasmic isolation and midbody/midbody ring release. Inhibition of the midbody ring–associated septins affects both stages, whereas the membrane-remodeling ESCRT machinery is only required for the second stage. In contrast to the idea that the midbody plays a central role in orchestrating abscission, both cytoplasmic isolation and midbody ring release occur normally in the absence of midbody microtubules. These results define distinct events during abscission and highlight the central role of the midbody ring, rather than midbody microtubules, in directing abscission.

Results

Cytoplasmic isolation occurs coincident with the completion of contractile ring constriction during the first division of the C. elegans embryo

To monitor contractile ring closure, we collected time-lapse 3D images of embryos expressing a GFP fusion with a pleckstrin homology (PH) domain that binds a phospholipid produced specifically on the plasma membrane (Audhya et al., 2005) and generated end-on views by rotating and projecting the data from the central portion of the embryo (Maddox et al., 2007). The last time when a hole can be detected is ~280 s after furrow initiation, a point we refer to as apparent closure (Fig. 1 A). To determine whether cytoplasmic isolation is coincident with apparent closure, we loaded caged carboxy-Q-rhodamine–labeled 10-kD dextran into embryos expressing the GFP-tagged plasma membrane probe by injection into the syncytial gonad of adult worms (Fig. S1 B). Diffusion was monitored by imaging at 5-s intervals after photoactivating the probe on one side of the embryo with a pulse of UV light. Before cytokinesis onset, the photoactivated probe equilibrated between the two halves of the embryo with a half-time of ~40 s; however, after apparent closure, there was no detectable equilibration (Fig. 1 B and Video 1). We conclude that the cytoplasm in the daughter cells becomes diffusional isolated coincident with the completion of contractile ring constriction.

The midbody/midbody ring from the first cytokinesis is released after anaphase of the subsequent cell division

In vertebrate cells, cytoplasmic isolation is thought to occur simultaneously with ESCRT-mediated scission (Steigemann et al., 2009; Guizetti et al., 2011). Scission releases the midbody into one of the daughter cells, if the bridge is severed on one side, or into the extracellular space, if it is cut on both sides (Chen et al., 2013). Midbodies are released into the extracellular space during the Q cell neuroblast divisions in C. elegans larva (Chai et al., 2012). However, older work suggested that the midbody/midbody ring from the first embryonic division remains after the completion of furrowing, in which it serves as a cortical site that guides centrosome rotation at the two-cell stage (Hyman, 1989; Waddle et al., 1994; Keating and White, 1998).

To determine whether the midbody/midbody ring are released, we used live-cell imaging to monitor fluorescently tagged fusions with two midbody components, mCherry-MKlp1[2N4] and GFP–Aurora B[AR]-2, and two components of the midbody ring, Myosin II[N2Y2]-GFP and GFP–CYK-7, a new contractile/midbody ring component that we recently identified (Green et al., 2011). Imaged embryos also expressed mCherry- or GFP-tagged fusions to label the plasma membrane. As contractile ring constriction completed, the two midbody markers were enveloped by the closing furrow and remained localized to a single tight focus embedded within the plasma membrane at the
Figure 2. The ESCRT machinery is required for midbody/midbody ring release. (A) Deconvolved wide-field image of an embryo stained for tubulin (cyan), Mklp1^ZEN-4, and ESCRT-I TSG-101 (n = 5 embryos). (B) Central plane confocal images of embryos expressing GFP-ESCRT-I MVB-12 (n = 6 embryos). Times are relative to anaphase of the second division. Dashed yellow lines mark the cell boundaries. The white arrowhead and yellow arrow mark the focus of the ESCRT-I MVB-12. (C) ESCRT-I tsg-101(RNAi) 365s after furrow initiation. Images at 5s intervals. (D) Midbody. Mklp1^ZEN-4/Plasma Membrane. cell–cell boundary, the intercellular bridge, for the next ~12 min (Fig. 1 C, yellow arrows; and Fig. S1 C; for a comparison of the intercellular bridge in the C. elegans embryo and vertebrate cells see Fig. S1 A). Coincident with anaphase of the second division (in the anterior AB cell; ~909 ± 102 s after furrow initiation), tiny pieces labeled with the plasma membrane marker were shed asymmetrically from the midbody region predominantly into the posterior cell (Fig. 1 C, white arrowheads). Approximately 200 s after the onset of membrane shedding (~1,100 s after initiation of the first division furrow), a focus containing both midbody markers was released into the posterior (P1) cell (Fig. 1 C, green arrows; Fig. S1 C; and Videos 2 and 3).

Imaging the midbody ring components revealed a similar pattern. As the contractile ring completed its constriction, both Myosin II<sup>MYV-2</sup>-GFP and GFP–CYK-7 remained concentrated in a tight focus in the center of the cell–cell boundary (Fig. 1 C, yellow arrows; Fig. S1 C; and Video 4). Beginning at anaphase of the second division, tiny fragments of both markers were shed coincident with fragments containing the plasma membrane marker (Fig. 1 C, white arrowheads). When the midbody was released, a large mass of both midbody ring markers was also released from the cell–cell boundary (Figs. 1 C, green arrows; Fig. S1 C; and Video 4). Tracking of the released midbody through the four-cell stage revealed that it was always retained in the EMS cell (Fig. S1 D). Although fragments staining for the plasma membrane marker, which binds phosphatidylinositol 4,5-bisphosphate, were associated with the midbody, the released midbody was not encaesed in this marker. Thus, the released midbody is either not encaesed in plasma membrane or the phosphatidylinositol 4,5-bisphosphate associated with the membrane surrounding the midbody is lost during release.

These results suggest that abscission in the early C. elegans embryo occurs in two stages (Fig. 2 F). During the first stage, the cytoplasm in the two daughter cells becomes diffusionally isolated, coincident with the completion of furrowing and formation of the intercellular bridge. During the second stage, which begins during anaphase of the subsequent cell division, the cortex surrounding the midbody is remodeled, releasing fragments containing plasma membrane and midbody ring markers. Remodeling culminates, ~200 s later, in the release of the midbody and midbody ring into the posterior cell.

**The ESCRT machinery is required for midbody/midbody ring release**

Midbody/midbody ring release could be mediated by ESCRT-dependent membrane scission (Henne et al., 2011; Agromayor and Martin-Serrano, 2013; McCullough et al., 2013). To investigate ESCRT function in the C. elegans embryo, we first localized the four-protein ESCRT-I complex by immunofluorescence against ESCRT-ITSG-101 and time-lapse imaging of a GFP fusion with ESCRT-IMVB-12. ESCRT-ITSG-101 colocalized with MKLP1<sup>ZEN-4</sup> to the midbody at the two-cell stage (Fig. 2 A). GFP–ESCRT-IMVB-12 was first detected at the midbody ~400 s after furrow initiation; levels subsequently increased (not depicted), and GFP–ESCRT-IMVB-12 was released with other midbody/midbody ring components after anaphase of the second division (Fig. 2 B and Video 5). To analyze ESCRT function, we depleted the ESCRT-I component TSG-101 because of its essential non-redundant role in membrane scission during cytokinesis (Carlton and Martin-Serrano, 2007; Morita et al., 2007). ESCRT-ITSG-101 depletion did not affect the timing of cytoplasmic isolation as assessed by monitoring photoactivated dextran diffusion (Fig. 2 C). During the second stage of abscission, fragments containing the plasma membrane marker and midbody ring markers were shed in ESCRT-Pre-101(RNAi) embryos (Fig. 2 E and Fig. S2) with timing similar to that in controls (onset = 9.5 ± 28 s in ESCRT-Pre-101(RNAi) embryos [n = 20] compared with 24 ± 41 s in control embryos [n = 66]). Strikingly, all four midbody/midbody ring components failed to release in the majority of ESCRT-Pre-101(RNAi) embryos (Fig. 2, D and E, yellow arrows; Fig. S2; and Video 6) and instead remained at the cell–cell interface even when monitored beyond the four-cell stage (Fig. 2, D and E). Consistent with previous work in C. elegans (Audhya et al., 2007; Michelet et al., 2009), furrows were not observed to open back up in ESCRT-inhibited embryos. We conclude that the ESCRT machinery is required to release the midbody/midbody ring from the cell–cell boundary but not for cytoplasmic isolation or to maintain a closed connection between the daughter cells.

**PRC1<sup>SPD-1</sup>** depletion prevents the formation of midbody microtubule bundles and Aurora B<sup>AIR-2</sup> targeting to the intercellular bridge

To examine the role of midbody microtubules in abscission, we depleted the microtubule-bundling protein PRC1<sup>SPD-1</sup>. As in other systems (Mollinari et al., 2002, 2005; Vernì et al., 2004; D’Avino et al., 2007), PRC1<sup>SPD-1</sup> inhibition in the C. elegans embryo prevents the formation of the microtubule bundles that make up the central spindle and blocks midbody assembly (Verbrugghe and White, 2004). We confirmed loss of midbody
Figure 3. PRC1Spd-1 depletion prevents the formation of midbody microtubule bundles and Aurora B AIR-2 targeting to the intercellular bridge. Kymographs of the GFP–β-tubulin signal in the midbody region are also shown. Times are seconds after furrow initiation. (B) Central plane confocal images on June 28, 2017 Downloaded from Published November 11, 2013
microtubules by imaging control and PRC1dpd-1(RNAi) embryos expressing GFP–β-tubulin and mCherry::histone. In control embryos, bundled microtubules in the central spindle compacted to form the midbody, which could be monitored for >400 s after furrow initiation. After this point, which corresponds to the onset of mitosis of the second cell division, midbody microtubules appeared to dissipate, suggesting that relatively few microtubules span the intracellular bridge at the time of midbody release in control C. elegans embryos. In contrast, no central spindle or midbody microtubules were detected at any stage in PRC1dpd-1(RNAi) embryos (Fig. 3 A and Video 7). Consistent with the absence of midbody microtubules, as the furrow closed during the first division, we could not detect any focus of GFP–Aurora B NPR-2 or mCherry–Mklp1ZEN-4 embedded within the cell–cell boundary in PRC1dpd-1(RNAi) embryos (Fig. 3, B and C). Although mCherry–Mklp1ZEN-4 did not localize to the initial cell–cell boundary in PRC1dpd-1(RNAi) embryos, a population of mCherry–Mklp1ZEN-4 was subsequently recruited to the midbody ring, becoming detectable ~500–600 s after furrow initiation (Fig. 3 C). In control embryos, the amount of mCherry–Mklp1ZEN-4 in the focus at the cell–cell boundary also increased over time (Fig. 3 C). In fixed abscission stage embryos, the freeze-crack fixation procedure occasionally causes the midbody ring to release from the midbody; in such embryos, Mklp1ZEN-4 localized to both the midbody and with Myosin II NMY-2 to the midbody ring (Fig. 3 D). These findings are consistent with work in vertebrate cells, suggesting that Mklp1 transitions from the midbody to the midbody ring as the intercellular bridge matures (Elia et al., 2011; Hu et al., 2012). To further confirm the loss of midbody microtubules in PRC1dpd-1(RNAi) embryos, we performed immunofluorescence in fixed embryos using Mklp1ZEN-4 as a marker for the location of the midbody ring. Whereas an intense microtubule bundle passed through the Mklp1ZEN-4-marked midbody ring in interphase two-cell stage control embryos, no tubulin fluorescence above background was detected passing through the Mklp1ZEN-4, marked midbody ring in PRC1dpd-1(RNAi) embryos (Fig. 3 E). We conclude that there are no detectable microtubule bundles passing through the intercellular bridge in PRC1dpd-1(RNAi) embryos. Our results further suggest that Mklp1ZEN-4 is a component of the midbody ring as well as the midbody and can be directly recruited to the midbody ring independent of midbody microtubules.

Furrow ingestion and cytoplasmic isolation occur with normal timing in the absence of midbody microtubules

Next, we monitored abscission in PRC1dpd-1(RNAi) embryos. The kinetics of contractile ring closure in PRC1dpd-1(RNAi) embryos were similar to those in controls, and apparent closure of the hole between the daughter cells occurred at a similar time point (Fig. 4 A). Monitoring of the contractile/midbody ring components Myosin II NMY-2–GFP, GFP–Septin UNC-59, and GFP–CYK-7 revealed that despite the absence of the midzone/midbody, the contractile ring closed and was converted into a midbody ring embedded in the cell–cell boundary with normal kinetics in PRC1dpd-1(RNAi) embryos (Fig. 4, B and C; and Video 5 B).

To determine whether midbody microtubules affect cytoplasmic isolation, we compared the diffusion of photoactivated 10-kD dextran probe at different time points after furrow initiation in control and PRC1dpd-1(RNAi) embryos. To quantitatively compare diffusion across the division plane at different times during furrow ingestion, we calculated the normalized intensity difference (NID) between the activated and unactivated halves of the embryo for each time point after photoactivation. Plotting the initial slope of the NID, which reflects the rate of probe diffusion across the division plane (Fig. 3 D), versus time revealed that the rate of diffusion across the division plane decreased with similar kinetics in control and PRC1dpd-1(RNAi) embryos (Fig. 3 E). In both cases, the rate progressively dropped until it reached 0 ~250 s after furrow initiation; the point at which diffusion stopped was reached slightly sooner (~30 s) in PRC1dpd-1(RNAi) embryos than in controls. We conclude that midbody microtubules are not required for cytoplasmic isolation.

Midbody microtubules are not required for membrane shedding, ESCRT recruitment, or midbody ring release

Next, we determined whether the absence of midbody microtubules affected membrane shedding or the fate of the midbody ring embedded in the cell–cell boundary. Imaging embryos coexpressing a fluorescent membrane probe with the midbody and midbody ring components revealed that PRC1dpd-1(RNAi) embryos shed fragments containing the plasma membrane marker and midbody ring markers at a time equivalent to that in controls (Fig. 5, A and C; and Video 8). The midbody ring markers Myosin II NMY-2–GFP, GFP–Septin UNC-59, and GFP–CYK-7 were embedded in the cell–cell boundary in the PRC1dpd-1(RNAi) embryos, and this focus was released into the posterior cell with normal timing (Fig. 5, B and C; and Video 8); Mklp1ZEN-4 recruited to the midbody ring was also released into the posterior cell (Fig. S3).
The septins are required for timely cytoplasmic isolation and for release of the midbody and midbody ring. The septins are midbody ring components across metazoans and have been shown to be important for abscission in vertebrate and Drosophila S2 cells (Estey et al., 2010; Kechad et al., 2012). In contrast to the combinatorial complexity of heterooligomeric septin complexes in humans, which have 13 different septins (Hall and Russell, 2012), C. elegans has only two septins (UNC-59 and UNC-61), and depletion of either is sufficient to disrupt septin recruitment to the contractile ring (Nguyen et al., 2000; John et al., 2007). To examine the effects of septin inhibition, we depleted the septin UNC-59. Consistent with this expectation, time-lapse imaging revealed recruitment and release of ESCRT-IMVB-12 from the cell–cell boundary (Fig. 4 D).

In summary, we conclude that despite the central role proposed for the midbody in orchestrating abscission, all the events we can monitor, including cytoplasmic isolation, ESCRT recruitment, membrane shedding, and release of the midbody ring into the posterior cell, succeed in the absence of midbody microtubules. These findings suggest that the midbody ring may play a greater role in scaffolding abscission than previously appreciated.

The fact that the midbody ring is released normally in PRC1spd-1(RNAi) embryos suggests that ESCRT can be directly recruited to the midbody ring. Consistent with this expectation, time-lapse imaging revealed recruitment and release of ESCRT-IMVB-12 from the cell–cell boundary (Fig. 4 D). In summary, we conclude that despite the central role proposed for the midbody ring, all the events we can monitor, including cytoplasmic isolation, ESCRT recruitment, membrane shedding, and release of the midbody ring into the posterior cell, succeed in the absence of midbody microtubules. These findings suggest that the midbody ring may play a greater role in scaffolding abscission than previously appreciated.

The septins are required for timely cytoplasmic isolation and for release of the midbody and midbody ring. The septins are midbody ring components across metazoans and have been shown to be important for abscission in vertebrate and Drosophila S2 cells (Estey et al., 2010; Kechad et al., 2012). In contrast to the combinatorial complexity of heterooligomeric septin complexes in humans, which have 13 different septins (Hall and Russell, 2012), C. elegans has only two septins (UNC-59 and UNC-61), and depletion of either is sufficient to disrupt septin recruitment to the contractile ring (Nguyen et al., 2000; John et al., 2007). previous work (Maddox et al., 2007), the furrow closed with similar kinetics to controls until the very end, when septin<sup>unc-59</sup>(RNAi) embryos persisted longer (≈20 s) with a small hole between the daughter cells (Fig. S4 A). To determine how septin depletion affects the timing of cytoplasmic isolation, we used the approach described in Fig. 4 D to monitor the diffusion of photoactivated 10-kD dextran across the division plane. Plotting the mean initial slope of the NID versus time revealed that the rate of diffusion across the division plane decreases with similar kinetics for the first 250 s after furrow initiation. However, at this point, the curves diverge, and the septin<sup>unc-59</sup>(RNAi) embryos remain diffusionally connected, with a small open channel between the daughter cells, for ≈140 s longer than controls (Fig. 6 A). We conclude that cytoplasmic isolation is substantially delayed by septin depletion.

Cytoplasmic isolation normally occurs as the contractile ring envelopes the midbody to form the intercellular bridge. The substantial delay in cytoplasmic isolation in the septin<sup>unc-59</sup>(RNAi) embryos suggested that this process was not occurring normally. Consistent with this idea, examination of mCherry-Mklp1<sup>ZEN-4</sup> and GFP–CYK-7 revealed that the midbody and midbody ring in septin<sup>unc-59</sup>(RNAi) embryos protruded out toward the cytoplasm in the posterior cell at the two-cell stage (Fig. 6, B and C, top). In contrast to control embryos, in which both mCherry-Mklp1<sup>ZEN-4</sup> and GFP–Aurora B<sup>AR-2</sup> remained at the cell–cell junction until midbody release, GFP–Aurora B<sup>AR-2</sup> gradually disappeared from the cell–cell junction in septin<sup>unc-59</sup>(RNAi) two-cell embryos coincident with entry of the daughter cells into mitosis (≈500 s before anaphase of the second division; Fig. 6 D). One possibility, suggested by the fact that midbody microtubules become difficult to detect during this time frame in control embryos, is that Aurora B<sup>AR-2</sup> transitions from midbody microtubules to a septin-dependent localization on the midbody ring coincident with mitotic entry. Shedding of plasma membrane and midbody ring markers was observed in septin<sup>unc-59</sup>(RNAi) embryos coincident with anaphase of the second division (onset = −19 ± 39 s in septin<sup>unc-59</sup>(RNAi) embryos [n = 20] compared with 24 ± 41 s in control embryos [n = 66]). At the time when the midbody and midbody ring were released into the posterior cell in control embryos, a focus containing mCherry–MKLP-1<sup>ZEN-4</sup>, Myosin II<sup>NMY-2</sup>–GFP, and GFP–CYK-7 protruded into the posterior cell of septin<sup>unc-59</sup>(RNAi) embryos but did not release (Figs. 6, B and C, yellow arrows; Fig. S4 B; and Video 9). After septin<sup>unc-59</sup>(RNAi), GFP–ESCRT-I<sup>TSG-101</sup>–GFP<sup>WB-12</sup> was recruited at levels comparable to controls (Fig. 6 E), but also failed to release, suggesting that the failure to release the midbody/midbody ring in septin<sup>unc-59</sup>(RNAi) embryos was not caused by failure to recruit the ESCRT machinery. We conclude that inhibition of the septins delays cytoplasmic isolation and results in the formation of a defective intercellular bridge; the intercellular bridge permits ESCRT machinery recruitment but cannot support ESCRT-mediated midbody/midbody ring release into the posterior cell.

### Septins and ESCRT function at different steps during abscission

Because both ESCRT and septin inhibitions result in failure of midbody/midbody ring release (Fig. 2, D and E; and Fig. 6, B and C), we performed a more careful comparison of these two conditions. In control embryos, expressing a GFP-tagged plasma membrane probe, the ingressing furrow enveloped the midbody, generating a smooth cell–cell boundary. In septin<sup>unc-59</sup>(RNAi) embryos, envelopment of the midbody by the plasma membrane was delayed, but the boundary remained smooth (Fig. 6 A). In ESCRT<sup>F<sub>TSG-101</sub></sup>(RNAi) embryos, the furrow enveloped the midbody with normal timing, consistent with our analysis indicating that cytoplasmic isolation occurs coincident with the completion of furrowing (Fig. 2 C); however, the intercellular bridge was often distended, suggesting the presence of an obstruction enveloped along with the midbody (Fig. 7 A and Video 10). An occlusion was also visible in the cell–cell boundary in differential interference contrast images of ESCRT<sup>F<sub>TSG-101</sub></sup>(RNAi) embryos (Fig. 7 A). Given that we do not observe ESCRT-I on the midbody/midbody ring until after cytoplasmic isolation, we suspect that the obstruction is a consequence of the effect of ESCRT inhibition on the formation of multivesicular bodies (Henne et al., 2011; McCullough et al., 2013), rather than caused by its role in midbody/midbody release. The midbody release defect in septin<sup>TSG-101</sup>-depleted embryos also differed from that in ESCRT-I<sup>TSG-101</sup>-depleted embryos. In septin<sup>TSG-101</sup>-depleted embryos, the midbody/midbody ring protruded into the posterior cell and did not appear to be encased in plasma membrane marker (Fig. 7 B and Fig. 6, B and C). In contrast, in ESCRT-I<sup>TSG-101</sup>-depleted embryos, the midbody/midbody ring was encased in a ring of plasma membrane embedded in the cell–cell boundary (Fig. 7 B). These distinct defects suggest that the septins and the ESCRT machinery function at different points during abscission (Fig. 8 and accompanying text in the Discussion).

### Discussion

Here, we use assays for cytoplasmic diffusion across the division plane and the fate of midbody and midbody ring components to analyze abscission in the early <i>C. elegans</i> embryo. Our results partition abscission into two distinct stages and define molecular components required for each stage (Fig. 8). Contrary to the proposal that abscission is orchestrated by the midbody, we show that all events during abscission that we can assay proceed normally in the absence of midbody microtubules. These results suggest that the midbody ring, rather than the midbody, orchestrates abscission in <i>C. elegans</i>.

### Abscission occurs in two stages: cytoplasmic isolation and midbody/midbody ring release

Previous work in HeLa cells suggested that the cessation of diffusion between the daughter cells and ESCRT-mediated scission are coupled events (Steigemann et al., 2009; Guizetti et al., 2011). In contrast, our characterization partitions abscission into two temporally distinct stages with different molecular requirements. During the first stage (Fig. 8, early abscission), the cytoplasm in the daughter cells becomes diffusionally isolated, coincident with the formation of an intercellular bridge containing the midbody and midbody ring. This step requires the septins but is ESCRT independent. During the second stage
The septins and ESCRT machinery function at different stages of abscission. (A, left) The central region of confocal images of control, septin\textsuperscript{unc-59}(RNAi), and ESCRT-\textsuperscript{p101}(RNAi) (>10 embryos for each condition) embryos expressing a GFP-tagged plasma membrane probe at different time points after furrow initiation. (right) Differential interference contrast (DIC) images of control, septin\textsuperscript{unc-59}(RNAi), or ESCRT-\textsuperscript{p101}(RNAi) embryos at the two-cell stage. The region in the yellow boxes is shown at higher magnification in the images to the right. (B) Central plane confocal images of four-cell stage control, septin\textsuperscript{unc-59}(RNAi), and ESCRT-\textsuperscript{p101}(RNAi) embryos expressing a fluorescently tagged plasma membrane probe along with the midbody marker mCherry-Mklp1\textsuperscript{ZEN-4} (top; \(n = 21\) control, 12 septin\textsuperscript{unc-59}(RNAi), and 16 ESCRT-\textsuperscript{p101}(RNAi) embryos) or the midbody ring marker GFP–CYK-7 (bottom; \(n = 19\) control, 12 septin\textsuperscript{unc-59}(RNAi), and 6 ESCRT-\textsuperscript{p101}(RNAi) embryos). The midbody is released into the posterior cell in control embryos, protrudes from cell–cell boundary in septin\textsuperscript{unc-59}(RNAi) embryos, and is enclosed within a plasma membrane–bound compartment embedded in the cell–cell boundary in ESCRT-\textsuperscript{p101}(RNAi) embryos. White boxes on the low magnification images mark the location of the region shown at higher magnification in the adjacent images. Bars, 5 \(\mu\)m.

(Fig. 8, late abscission), which occurs concurrent with the subsequent division of the daughter cells, the intercellular bridge is remodeled, as indicated by plasma membrane shedding, followed by the ESCRT-dependent release of the midbody/midbody ring. Remodeling of the intercellular bridge releases fragments containing plasma membrane and midbody ring markers (Fig. 8, late abscission–membrane shedding). Membrane shedding is observed after septin\textsuperscript{unc-59}, PRC1\textsuperscript{SPD-1}, and ESCRT-\textsuperscript{I\textsuperscript{p101}} depletion. An attractive possibility based on these results is that shedding is the result of a septin- and ESCRT-independent membrane remodeling event that acts on the intercellular bridge in conjunction with the ESCRT machinery to release the midbody/midbody ring. Additional work targeting some of the membrane trafficking components implicated in abscission (Schiel and Prekeris, 2013) will be needed to determine how membrane shedding occurs and to assess its importance to abscission.

Our results show that the septins are required for release of the midbody/midbody ring as well as for timely cytoplasmic isolation. In septin-inhibited embryos, cytoplasmic isolation eventually occurs, but the midbody/midbody ring ends up in an aberrant configuration protruding into the posterior cell (Fig. 8). Thus, when the septins are absent, a septin-independent process is able to bring about cytoplasmic isolation, albeit in an aberrant way that does not result in the midbody/midbody ring being properly enveloped within the cell–cell boundary. In septin-depleted embryos, the ESCRT machinery is recruited, but the midbody/midbody ring fails to release. An appealing possibility is that release fails because
The midbody ring orchestrates abscission in the absence of midbody microtubules

A central focus of our work was to test the hypothesis that the microtubule-based midbody serves as the platform that brings together the abscission machinery. Remarkably, all of the events that we monitored during both stages of abscission, cytoplasmic isolation, shedding of membrane and midbody ring components, and midbody/midbody ring release, all succeeded when we prevented midbody assembly by inhibiting the microtubule-bundling protein PRC1 SPD-1. This result suggests that the midbody is not an essential component of the diffusion barrier between daughter cells; the midbody ring can close the hole between the daughter cells sufficiently to block cytoplasmic diffusion.

Midbody microtubules are also proposed to scaffold the recruitment of membrane trafficking components that narrow the intercellular bridge before scission (Schiel and Prekeris, 2013) and of the ESCRT machinery to promote scission (Fededa and Gerlich, 2012; Agromayor and Martin-Serrano, 2013). Our results suggest that the midbody ring, in the absence of midbody microtubules, is sufficient to direct remodeling of the intercellular the aberrant cell–cell junction that forms is unable to serve as a substrate for the ESCRT-mediated scission machinery.

In the C. elegans embryo, the midbody/midbody ring is released one cell cycle after the intercellular bridge is formed. We do not know what mechanical or cell cycle cues control the timing of midbody release. Although cell cycle regulation seems to be the most likely trigger, recent work in human cells has shown that a local reduction in tension promotes abscission in vertebrate cells (Lafaurie-Janvore et al., 2013). It will therefore be interesting to determine whether midbody release in C. elegans is controlled by cell cycle cues or by an alteration in cortical tension induced by cell shape changes at anaphase of the second division.
bridge to allow it to attain a conformation conducive to cleavage and to recruit the ESCRT machinery that releases the midbody/midbody ring. Previous work in HeLa cells showed that PRC1^SPO1-depletion results in an abscission defect (Mollinari et al., 2005). These authors reported that furrowing proceeded to completion, and cells remained connected by an intercellular bridge for ~1 h, the usual time between formation of the intercellular bridge and scission (Steigemann et al., 2009; Guizetti et al., 2011) before the furrow regressed. These results suggest that the defect in these cells might not be in the formation of the intercellular bridge but in the execution of the final scission event (Mollinari et al., 2005). Additional work using higher resolution assays for the different steps in abscission will be needed to determine which step in abscission is blocked in the absence of PRC1 and whether remodeling of the intercellular bridge in human cells is affected by the absence of midbody microtubules.

In human cells, centralspindlin recruits CEP55, which recruits the ESCRT machinery to promote scission (Fabbro et al., 2005; Zhao et al., 2006; Carlton and Martin-Serrano, 2007; Morita et al., 2007; Carlton et al., 2008; Lee et al., 2008; Bastos and Barr, 2010). Because C. elegans (and Drosophila) lack CEP55 homologues, the ESCRT machinery is likely recruited in these systems either by direct binding to centralspindlin or another midbody ring component. Direct binding to centralspindlin is an attractive possibility, as centralspindlin is recruited directly to the midbody ring with similar timing to the ESCRT complex in PRC1^SPO1-depleted embryos (Fig. 3 C). As centralspindlin also transitions from the midbody to the midbody ring in human cells (Elia et al., 2011; Hu et al., 2012), it is possible that centralspindlin and the ESCRT machinery are recruited to the abscission site in human cells lacking midbody microtubules, as they are in C. elegans, but that scission fails as a result of a role for midbody microtubules downstream of ESCRT recruitment. Additional experiments will be needed to resolve this issue.

Abscission phase in vivo
Our work provides a detailed molecular analysis of abscission in an organismal context. One of our most interesting findings is how robust abscission is in the C. elegans embryo. Cell–cell boundaries form and remain stably closed in cells lacking midbody microtubules, depleted of the ESCRT machinery, and depleted of the septins, all conditions previously shown to result in abscission failure and reopening of the intercellular bridge in vertebrate cells (Mollinari et al., 2005; Estey et al., 2010; Caballe and Martin-Serrano, 2011). Consistent with this finding, cell–cell boundaries have previously been shown to form and remain closed, even in the presence of chromatin obstructions (Bembenek et al., 2013). The fact that we did not see regression of cell–cell boundaries under any of the conditions we tested suggests that redundant mechanisms are in place to ensure the successful formation of stable cell–cell boundaries in intact organisms. The nature of these mechanisms will be an interesting area to explore in future work.

Materials and methods

C. elegans strains
C. elegans strains (genotypes listed in Table S1) were maintained at 20°C. As the gfp::air-2 transgene in OD448 is subject to silencing, experiments with this line were performed by singling adult OD448 hermaphrodites after confirming that they were positive for the GFP::AIR-2 marker and using L4 progeny from these animals for experiments. GFP::AIR-2 expression was verified in the pronuclei of dissected embryos before midbody filming.

RNAi
Double-stranded RNAs (dsRNAs) were prepared by using oligonucleotides (oligos) containing T3 or T7 promoters (listed in Table S2) to amplify regions from genomic N2 DNA. PCR reactions were cleaned (QIAGEN) and used as templates for T3 and T7 transcription reactions (25 µl; Ambion), which were cleaned using a MEGAClear kit (Ambion) and combined. RNA eluted with 50 µl H₂O was mixed with 3x injection buffer (25 µl; 1x = 20 mM KPO₄, pH 7.5, 3 mM K-Citrate, pH 7.5, and 2% PEG 6000) and annealed by heating at 68°C for 30 min followed by 27°C for 30 min. dsRNA was injected into L4 hermaphrodite worms 48 h before imaging. For photoactivation experiments, the gonads of dsRNA-injected worms were reinserted with CMNCBZ-caged carboxy-G-rodamine dextran (Invitrogen and Molecular Probes) 43 h later (5 h before imaging).

Photoactivation experiments
Adult OD58 (Audhya et al., 2005) hermaphrodites, either injected 43 h previously with dsRNA or uncontrolled, were injected in both gonads with a 10,000 molecular weight dextran conjugate of CMNCBZ-caged carboxy-G-rodamine dissolved in injection buffer (20 mM KPO₄, pH 7.5, 3 mM K-Citrate, pH 7.5, and 2% PEG 6000) and annealed by heating at 68°C for 30 min. Worms were allowed to recover at 20°C for 5 h on plates with food. We note that ESCRT^SPO1(RNAi) adversely affected cuticle formation in the adult worm, making reinjection more difficult than for other depletion conditions; shortened, more rigid needles were used to inject these worms. Dissected embryos were mounted for filming by transferring selected embryos to a preformed 2% agarose pad positioned on a microscope slide with a mouth pipette and covering them with an 18 x 18-mm coverslip. Photoactivation and imaging of dissected embryos were performed on a deconvolution microscope (DeltaVision; Applied Precision) equipped with a charge-coupled device (CCD) camera (CoolSNAP; Roper Scientific). Mounted embryos were positioned so that half of the embryo was blocked from light exposure when the field diaphragm was closed completely. Prephotoactivation images were taken with the field diaphragm open (at 5-s intervals). Then, the field diaphragm was manually closed, and the embryo was hit with a 2-s pulse of UV light using a 100-W mercury arc lamp (Chiu Technical Corporation) to uncage the probe and produce orange fluorescence (excitation/emission of ~545/575 nm). The field diaphragm was reopened, and a single central z section was acquired at 5-s intervals for 100 s using a 60x, NA 1.4 Plan Apochromat objective (Olympus) with 2 x 2 binning.

Images were analyzed in Meta Morph (Molecular Devices) by positioning two 90-pixel diameter circles on either side of the furrow site (activated versus unactivated sides) and logging the total intensity in the rhodamine channel over the time series. The total value for each side before photoactivation (background) was subtracted from the total value at each time point after photoactivation to eliminate baseline rhodamine signal. The NID (NID = [Aₜ − Ut]/[A₀ − Ut]) was calculated for each time point, at which A₀ − Ut was the difference between the fluorescence intensities of the activated and unactivated sides at time t, and Aₜ − Ut was the difference between the fluorescence intensities of the activated and unactivated sides at time 0. For the control plot (Fig. 4 E and Fig. 6 A), data from 55 independent photoactivations in 42 embryos were pooled, yielding a mean of 11.7 measured slopes per 10-s interval. For the septin(RNAi) plot (Fig. 6 A), data from 61 independent photoactivations in 33 embryos were pooled yielding a mean of 9.9 measured slopes per 10-s interval. To generate the graphs in Fig. 4 E and Fig. 6 A, the slope data from all of the photoactivation events were pooled, and the mean value of the slope for each 10-s interval centered on the plotted point was calculated.
Plots of furrow diameter versus time

Plots of furrow diameter versus time (Fig. 1 A, Fig. 4 A, and Fig. 5 A) were generated by collecting 12-plane z series (2.5-µm intervals) at 20-s time intervals of embryos from the strain OD58 during the course of the first embryonic division on a deconvolution microscope (DeltaVision) equipped with a CCD camera [CoolSNAP]. DeltaVision software was used to rotate the data from the central region of the embryo containing the contractile ring by 90° and generate a maximum intensity projection and to measure the diameter of the hole at each time point.

Midbody/midbody ring release experiments

One-cell stage embryos were dissected from gravid adult hermaphrodites from the strains OD449, OD183, OD1268, OD448, OD178, OD868, and OD227 in M9 medium [Brenner, 1974] and were mounted for imaging by transferring them to a 2% agarose pad with a mouth pipette and covering them with a 18 × 18-mm coverslip. Images were acquired with either (a) an confocal system (Revolution XD; Andor Technology) with a confocal scanner unit (CSU-10; Yokogawa Corporation of America) mounted on an inverted microscope [TE2000-E; Nikon] equipped with a 60×, 1.4 NA Plan Apochromat lens, solid-state 100-nW lasers, and a high-resolution interline CCD camera [Clara [Andor Technology; 2 × 2 binning] or iXon [Andor Technology; 1 × 1 binning]] or (b) a microscope (Axio Observer.Z1; Carl Zeiss) equipped with a CCD camera [ORCA-ER; Hamamatsu Photonics] with 2 × 2 binning. Embryos were imaged every 20 s in a single image plane, manually adjusting to keep the midbody in focus, until ~800 s after furrow initiation. To track the dynamics of the midbody before and at midbody release, an 8 × 1–µm z series was then collected every 20 s until the embryo reached the four-cell stage. Single planes containing the midbody remnant were identified and stitched together to generate movies using MetaMorph software. Live imaging of microtubules (Fig. 3 A) was performed by acquiring a central eight-plane z series (1-µm steps) at 20-s time intervals throughout the first and second division; a single image plane, containing microtubules, at each time point was selected and stitched together to track changes at the midbody. Timing of membrane shedding onset and midbody/midbody ring release was gauged relative to (a) furrow initiation, which we define as the first distended intercellular bridge. **Figure S1. The midbody and midbody ring from the first division end up in the EMS cell at the four-cell stage.** (A) Schematic illustrates the relative geometry of the intercellular bridges in cultured vertebrate cells and during the first division of the *C. elegans* embryo. MTs, microtubules. (B) Schematic summarizing the method used to generate embryos loaded with 10kD caged carboxy-Q-rhodamine–labeled dextran. 10kD dextran was injected into the syncytial germline of adult hermaphrodite worms. After 5 h, injected worms were dissected to obtain one-cell stage embryos loaded with dextran. (C) Central plane fluorescence confocal images are shown for embryos expressing the mCherry-tagged plasma membrane probe along with either the midbody marker GFP–Aurora BIR-2 (n = 9 embryos) or the midbody ring marker GFP–CYK-7 (n = 19 embryos). (D) Schematic illustrates the first three embryonic divisions, giving rise to a four-cell embryo consisting of AB.p, AB.a, EMS, and P2 cells. Central plane fluorescence confocal images are shown for four-cell stage embryos expressing a fluorescent plasma membrane probe along with either the midbody marker GFP–Aurora BIR-2 (top left) and mCherry-MKLP1ZEN-4 (top right) or the midbody ring markers GFP–CYK-7 (bottom left) or Myosin MNMY-2–GFP (bottom right). The released midbody is observed in the EMS cell (n = 66 four-cell embryos scored, total for all markers). White boxes on the low magnification images mark the location of the region shown at higher magnification in the adjacent images. Bars, 5 µm.
Figure S2. **Midbody and midbody ring release requires ESCRT-I.** Central plane fluorescence confocal images of ESCRT-I \textsuperscript{tsg-101} (RNAi) embryos expressing an mCherry-tagged plasma membrane probe along with either the midbody marker GFP–Aurora B\textsuperscript{AIR-2} (n = 6 embryos) or the midbody ring marker Myosin II\textsuperscript{NMY-2}–GFP (n = 18 embryos). Released fragments marked with the plasma membrane probe are indicated (white arrowheads). The midbody/midbody ring from the first division that fails to be released (yellow arrows), and the tips of the ingressing furrow from the second embryonic division (asterisks) are indicated. Times are relative to anaphase of the second division. White boxes on the low magnification images mark the location of the region shown at higher magnification in the adjacent images. Bars, 5 µm.

Figure S3. **Mklp1\textsuperscript{ZEN-4} is recruited to the midbody ring and is released into the posterior cell in PRC1\textsuperscript{spd-1} (RNAi) embryos.** Representative deconvolved wide-field fluorescence images (single z plane) of control or PRC1\textsuperscript{spd-1} (RNAi) four-cell stage embryos stained for Mklp1\textsuperscript{ZEN-4}, tubulin, and DNA. A released focus of Mklp4\textsuperscript{ZEN-4} is observed in the EMS cell in both conditions (white arrowheads). Bar, 5 µm.
Scaffolding of abscission by the midbody ring

Figure S4. The septins are required for midbody ring release. (A) Graph plotting mean furrow diameter versus time, measured as in Fig. 1A, for the first division of control and septin<sup>unc-59</sup>(RNAi) (n = 10 embryos for each condition). Control data are reproduced from Fig. 1A. Error bars are the SDs. Arrow denotes the last time point with a measurable opening (apparent closure). (B) Central plane fluorescence confocal images of septin<sup>unc-59</sup>(RNAi) embryos expressing a fluorescently tagged plasma membrane probe along with the midbody ring marker Myosin II<sup>NMY-2</sup>–GFP (n = 7 embryos). Times are relative to anaphase of the second division. Released fragments marked with the plasma membrane probe are indicated (white arrowhead). Yellow arrows point to the midbody/midbody ring from the first division, which fails to be released. Asterisks mark the tip of the ingressing furrow from the second embryonic division. (C) Control (left) or septin<sup>unc-59</sup>(RNAi) (right) embryos expressing a GFP-labeled plasma membrane probe (left images in each set) were loaded with caged 10-kD carboxy-Q-rhodamine–labeled dextran (middle and right images, shown in pseudocolor to enhance contrast). The dextran in one half of the embryos was photoactivated in late-stage embryos (photoactivated at ~250 s after furrow initiation [control] or ~290 s after furrow initiation [septin<sup>unc-59</sup>(RNAi)]), and embryos were imaged every 5 s to monitor diffusion. Central plane images show the embryos before activation (top row), immediately after activation (middle row), and >100 s after activation (bottom row). (right) Insets show magnified view of the unactivated half of each embryo at the noted time points. In the control embryo, no change is observed in the fluorescence on the unactivated side of the embryo over the 125 s after photoactivation, indicating that there is no diffusion of the activated probe across the nascent cell–cell boundary. In contrast, there is a small but detectable change in the amount of probe in the unactivated half of the septin<sup>unc-59</sup>(RNAi) embryo over the 95 s after activation, confirming that the probe is still able to diffuse across the cell–cell boundary. White boxes on the low magnification images mark the location of the region shown at higher magnification in the adjacent images. Bars, 5 μm.

Video 1. **Photoactivated dextran equilibrates rapidly between the two halves of the one-cell stage C. elegans embryo and is restricted to one half of the two-cell stage C. elegans embryo.** Examples of a control one-cell stage embryo that was photoactivated before cytokinesis onset (left) and a two-cell stage embryo that was photoactivated ~350 s after the onset of furrow ingression during the first cytokinesis (right); both cells express a GFP-labeled plasma membrane probe and were preloaded with caged carboxy-Q-rhodamine–labeled 10kD dextran. The photoactivated dextran (top) and the GFP-tagged plasma membrane (bottom) are shown with the fluorescence intensity presented in pseudocolor to allow visualization of dextran probe equilibration over time. Central section fluorescence images were acquired every 5 s before and after photoactivation using a DeltaVision deconvolution wide-field microscope. Playback rate is 30x real time (six frames/second).

Video 2. **The Mklp1^{T23N4}-marked midbody/midbody ring from the first division is released into the posterior cell coincident with anaphase of the second cell division.** Example of a control two-cell embryo, expressing a fluorescently tagged plasma membrane probe (red) along with the midbody/midbody ring marker mCherry-Mklp1^{T23N4} (green). An 8 x 1-µm confocal z series was collected every 20 s, and planes containing the midbody marker were selected and stitched together to allow for tracking of midbody fate as the embryo progressed through the second round of cell division. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120x real time (six frames/second).

Video 3. **The Aurora B^{48R2}-marked midbody from the first division is released into the posterior cell coincident with anaphase of the second cell division.** Example of a control two-cell embryo, expressing a fluorescently tagged plasma membrane probe (red) along with the midbody marker GFP–Aurora B^{48R2} (green). An 8 x 1-µm confocal z series was collected every 20 s, and planes containing the midbody marker were selected and stitched together to allow for tracking of midbody fate as the embryo progressed through the second cell division. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120x real time (six frames/second).

Video 4. **The CYK-7– and Myosin II^{150R2}-marked midbody rings from the first division are released into the posterior cell coincident with anaphase of the second cell division.** Examples of a control two-cell embryo expressing a fluorescently tagged plasma membrane probe (red) along with the midbody ring marker GFP–CYK-7 (green, left) or Myosin II^{150R2}-GFP (green, right). An 8 x 1-µm confocal z series was collected every 20 s, and planes containing the midbody ring marker were selected and stitched together to allow for tracking of midbody fate as the embryo progressed through the second division. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120x real time (six frames/second).

Video 5. **ESCRT-I^{P631T2} localizes to the midbody and is released into the posterior cell coincident with anaphase of the second cell division.** Example of a control two-cell embryo expressing GFP–ESCRT-I^{P631T2}. An 8 x 1-µm confocal z series was collected every 20 s, and planes containing the midbody marker were selected and stitched together. Fragments containing GFP–ESCRT-I^{P631T2} are released beginning at anaphase of the second embryonic division, and this is followed by release of the midbody shortly thereafter. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120x real time (six frames/second).

Video 6. **The Aurora B^{48R2}-marked midbody and the CYK-7–marked midbody ring fail to release into the posterior cell after depletion of ESCRT-I^{P631T2}.** Examples of an ESCRT-I^{P631T2} (RNAi) two-cell embryo, expressing a fluorescently tagged plasma membrane probe (red) along with the midbody marker GFP–Aurora B^{48R2} (green, left) or the midbody ring marker GFP–CYK-7 (green, right). An 8 x 1-µm confocal z series was collected every 20 s, and planes containing the midbody marker were selected and stitched together to allow for tracking of midbody fate as the embryo progressed through the second round of cell division. In the absence of ESCRT-I, the GFP–Aurora B^{48R2}–marked midbody and the GFP–CYK-7–marked midbody ring remained embedded in the cell–cell boundary. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120x real time (six frames/second).

Video 7. **The midbody fails to form in the absence of PRC1^{D51}.** Example control (left) and PRC1^{D51} (RNAi) (right) embryos expressing fluorescently tagged GFP–tubulin (green) and mCherry–histone H2B (red). An 8 x 1-µm confocal z series was collected every 20 s, and central planes were selected and stitched together. Playback rate is 120x real time (six frames/second).
Video 8. After PRC1\(^{spd-1}\) depletion, Aurora B\(^{AR-2}\) is not recruited to the cell–cell boundary, but the CYK-7–marked midbody ring from the first division is released into the posterior cell with normal kinetics. (first image series) Example of a PRC1\(^{spd-1}\) [RNAi] two-cell embryo expressing a fluorescently tagged plasma membrane probe (red) along with the midbody marker GFP–Aurora B\(^{AR-2}\) (green). (second image series) A single central plane was collected every 20 s in the central plane of the embryo until \(~200\) s before the second embryonic division (\(~700\) s after furrow initiation), after which point an \(8 \times 1–\mu m\) confocal z series was collected every 20 s. Optimal image planes were selected and stitched together throughout the subsequent embryonic divisions. Example of a PRC1\(^{spd-1}\) [RNAi] two-cell embryo expressing a fluorescently tagged plasma membrane probe (red) along with the midbody ring marker GFP–CYK-7 (green). An \(8 \times 1–\mu m\) confocal z series was collected every 20 s, and planes containing the midbody ring marker were selected and stitched together to allow for tracking of midbody ring fate as the embryo progressed through the second division. In PRC1\(^{spd-1}\)-depleted embryos, the midbody ring marker was recruited to the cell–cell junction and released with normal timing after anaphase of the second embryonic division. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120× real time [six frames/second].

Video 9. The Mklp1\(^{ZEN-4}\)-marked or CYK-7–marked midbody/midbody ring protrudes into the posterior cell and fails to release from the cell–cell boundary after depletion of septin\(^{unc-59}\). Examples of septin\(^{unc-59}\) [RNAi] two-cell embryos expressing a fluorescently tagged plasma membrane probe (red) along with mCherry-Mklp1\(^{ZEN-4}\) (green, left) or GFP–CYK-7 (green, right). An \(8 \times 1–\mu m\) confocal z series was collected every 20 s, and planes containing the midbody marker were selected and stitched together to allow for tracking of midbody fate as the embryo progressed through the second round of cell division. In septin-depleted embryos, the Mklp1\(^{ZEN-4}\) or CYK-7 focus protrudes into the posterior cells and ultimately fails to release from the cell–cell boundary. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120× real time [six frames/second].

Video 10. ESCRT\(^{[50-101]}\) depletion leads to formation of a distended intercellular bridge. Z series (11 planes at 2.5-µm intervals) of control (left) and ESCRT\(^{[50-101]}\) [RNAi] embryos (right) were collected every 20 s during cytokinesis of the first embryonic division. The image plane containing the widest furrow diameter for each time point was selected and stitched together to track the final stages of furrow closure. In control embryos, the furrow envelopes the midbody in plasma membrane generating smooth cell–cell boundary. In ESCRT\(^{[50-101]}\) [RNAi] embryos, the furrow envelopes the midbody with normal timing; however, the intercellular bridge that forms is distended, forming a ring that is clearly visible at the light microscopy level, suggesting the presence of an obstruction that is enveloped along with the midbody. Images were acquired using a spinning-disk confocal system mounted on an inverted microscope. Playback rate is 120× real time [six frames/second].
