The ubiquitous clathrin heavy chain (CHC), the main component of clathrin-coated vesicles, is well characterized for its role in intracellular membrane traffic and endocytosis from the plasma membrane (PM). Here, we demonstrate that in skeletal muscle CHC regulates the formation and maintenance of PM–sarcomere attachment sites also known as costameres. We show that clathrin forms large coated lattices associated with actin filaments and the muscle-specific isoform of α-actinin at the PM of differentiated myotubes. Depletion of CHC in myotubes induced a loss of actin and α-actinin sarcomeric organization, whereas CHC depletion in vivo induced a loss of contractile force due to the detachment of sarcomeres from the PM. Our results suggest that CHC contributes to the formation and maintenance of the contractile apparatus through interactions with costameric proteins and highlight an unconventional role for CHC in skeletal muscle that may be relevant to pathophysiology of neuromuscular disorders.

Introduction

Clathrin is composed of trimerized heavy chains (CHCs) with bound light chains (CLCs) and assembles to form a membrane coat. The clathrin lattice formation on cellular membranes is initiated by clathrin adaptors that are drawn into the lattice and trigger clathrin-coated vesicle (CCV) budding at various subcellular compartments (Pearse and Robinson, 1990; Kirchhausen, 1999; Brodsky, 2012). Once the invagination process has initiated, dynamin family members associate with the neck of the forming pit, recruit additional proteins including actin, and allow the scission of the coated vesicle (Fujimoto et al., 2000; Merrifield et al., 2002). The role of dynamin 2 (DNM2) in skeletal muscle has received considerable attention because the autosomal-dominant form of centronuclear myopathy (CNM) has been linked to mutations in the DNM2 gene (Bitoun et al., 2005). DNM2 is involved in various cellular processes, but to date it remains unclear whether its role in CCV fission is implicated in centronuclear myopathy.

Several recent studies have proposed a role for clathrin and dynamin in actin organization that is distinct from coated vesicle formation (Schafer et al., 2002; Veiga et al., 2007; Saffarian et al., 2009; Bonazzi et al., 2011, 2012). Intriguingly, a role for clathrin in myofibril assembly was previously proposed (Kaufman et al., 1990), and several teams have reported direct protein–protein interaction between CHC, α-actinin, and vinculin, two focal adhesion proteins crucial for muscle function (Schook et al., 1979; Burridge et al., 1980; Merisko, 1985;...
muscle costamereogenesis and costamere maintenance. We show that clathrin associates with $\alpha$-actinin at the surface of myotubes and forms large plaques that are associated with actin filaments. Depletion of CHC induces severe defects in $\alpha$-actinin distribution and subsequently leads to defective costamere formation in vitro and induces impairment of contractile properties associated with structural abnormalities including sarcomere disorganization as well as detachment of the sarcomeres from the sarcolemma in vivo.

**Results**

**CHC is a component of the costameric complex in skeletal muscle**

In adult skeletal muscle, DNM2 and CHC are both localized at the level of the I-band and present a striated pattern that overlaps with the muscle-specific $\alpha$-actinin (isoform 2) staining

Merisko et al., 1988; Fausser et al., 1993). $\alpha$-Actinin and vinculin are expressed in both skeletal and cardiac muscles, where they are localized to a specialized compartment called the “costamere.”

Costameres, muscle-specific adhesion sites, are subsarcolemmal protein assemblies circumferentially aligned in register with Z-disks of peripheral myofibrils. They were originally described as electron-dense plaques rich in the focal adhesion protein vinculin, and function as attachment complexes (Pardo et al., 1983a,b; Shear and Bloch, 1985). They are located between the plasma membrane and myofibrils and play both a mechanical and a signaling role during contraction, transmitting force from the contractile apparatus to the ECM in order to stabilize skeletal muscle fibers. They are considered as the “Achilles’ Heel” of skeletal muscle because, when disrupted, they directly contribute to the development of several distinct myopathies (Blake et al., 2002; Ervasti, 2003). In the present work, we have addressed the role played by CHC in skeletal muscle costamereogenesis and costamere maintenance. We show that clathrin associates with $\alpha$-actinin at the surface of myotubes and forms large plaques that are associated with actin filaments. Depletion of CHC induces severe defects in $\alpha$-actinin distribution and subsequently leads to defective costamere formation in vitro and induces impairment of contractile properties associated with structural abnormalities including sarcomere disorganization as well as detachment of the sarcomeres from the sarcolemma in vivo.

Figure 1. **CHC association with $\alpha$-actinin2 in adult skeletal muscle.** (A) Confocal sections of mouse skeletal muscle were processed for double-immunofluorescent labeling of DNM2 (red) and $\alpha$-actinin (green) or CHC (red) and $\alpha$-actinin (green). Bars, 10 µm. (B) The fluorescence intensity as a function of distance on the fiber was plotted for eight successive striations, and was reported on the graph for each labeling. The green curve corresponds to the green immunolabeling, and the red curve corresponds to the red labeling. (C and D) CHC localization in mouse dissociated FDB fibers. (C) Confocal sections of fibers processed for immunofluorescent labeling with the monoclonal antibody against CHC (X22, green). Bars: (main panel) 10 µm; (inset) 2 µm. (D) XZ and YZ projections of confocal optical sections illustrated in C. Bars, 10 µm. (E) Immunoblot of proteins associated with CHC, $\alpha$-actinin (isoform 2), vinculin, or control immunoprecipitates from mouse muscle lysates and 1–5% lysate input. Bands for coimmunoprecipitated CHC, $\alpha$-actinin (isoform 2), vinculin, talin, or CLC are indicated at the right.
Clathrin heavy chain is required for sarcomere organization • Vassilopoulos et al.

Amounts of vinculin and talin. Additionally, minor amounts of α-actinin are detected upon clathrin immunoprecipitation while vinculin coimmunoprecipitates talin efficiently and some α-actinin, but not clathrin. This suggests that part of the α-actinin pool is associated with clathrin in a complex distinct from the vinculin–talin–α-actinin complex.

We further characterized the sites of interaction between CHC and α-actinin during the early steps of differentiation in primary myotubes and showed that these proteins partially colocalize along the plasma membrane (PM) after 4 d of differentiation (Fig. 2 A). By subcellular fractionation, we observed an association between α-actinin and CHC in the PM fraction of fibroblasts, myoblasts, and differentiated myotubes. This association was stronger in differentiated myotubes as the levels of α-actinin expression increase (Fig. 2, B and C). In addition, we detected α-actin in both CHC and α-actinin immunoprecipitates from muscle cells. Several adaptor proteins are required (Fig. 1, A and B; Kaufman et al., 1990; Butler et al., 1997; Towler et al., 2004; Durieux et al., 2010; Cowling et al., 2011). Using confocal optical sectioning and 3D reconstruction, we demonstrated that this striated labeling was mainly present at the surface of dissociated fibers (Fig. 1, C and D). Analysis of the compartment labeled by anti-CHC antibodies on adult skeletal muscle using electron microscopy revealed that clathrin is present along the sarcolemma and localizes at sites that correspond to contacts between sarcolemma and Z-discs, which are also densely stained with tannic acid (Fig. S1, A and B). As several studies have described a direct association between α-actinin and vinculin with clathrin (Schook et al., 1979; Burridge et al., 1980; Merisko, 1985; Merisko et al., 1988; Fausser et al., 1993), we then assessed the association between clathrin and the α-actinin–vinculin–talin complex in adult mouse skeletal muscle (Fig. 1 E). We observed coimmunoprecipitation of CHC and CLC upon α-actinin immunoprecipitation, but only minor amounts of vinculin and talin. Additionally, minor amounts of α-actin are detected upon clathrin immunoprecipitation while vinculin coimmunoprecipitates talin efficiently and some α-actinin, but not clathrin. This suggests that part of the α-actinin pool is associated with clathrin in a complex distinct from the vinculin–talin–α-actinin complex.

Figure 2. CHC association with α-actinin2 and actin at the PM of differentiated myotubes. (A) Localization of α-actinin (green) and CHC (red) in mouse primary myotubes differentiated for 4 d. Inset in Overlay panel is displayed on the right. (B) Immunoblot analysis of proteins associated with CHC or control immunoprecipitates from subcellular fractions (plasma membrane, PM and cytosol, CYT) of 3T3 fibroblasts (FB), undifferentiated C2C12 (MB), and differentiated C2C12 cells (MT). (C) Immunoblot analysis of proteins associated with α-actinin or control immunoprecipitates from subcellular fractions (PM and CYT) of 3T3 fibroblasts (FB), undifferentiated C2C12 (MB), and differentiated C2C12 cells (MT). (D) Confocal microscopy of AP2 (green) and CHC (red) in differentiated C2C12 skeletal muscle cells. The left panel displays images from the top of the myotube and the right panel displays images from the middle of the myotube. Arrows indicate large clusters of colocalization between AP2 and CHC and arrowheads indicate intracellular clusters near the nuclei positive for CHC and negative for AP2. (E) XZ and YZ projections of serial confocal sections are shown on the overlay. Bar, 10 µm.
Deep-etch rotary replication and electron microscopy (Heuser, 1980). We showed that clathrin forms two distinct coated structures, i.e., large plaques that contain much more polymerized clathrin that would be required to form a single vesicle (pseudocolored in red in Fig. 3, D and F) and coated vesicles found in regions devoid of plaques (Fig. 3, D and F; and Fig. S1, C–G). Using clathrin antibodies we were able to confirm that CHC was indeed the proteinaceous material composing these structures (Fig. S1, C–K). As expected, α-actinin strongly labeled dense longitudinally organized actin filament bundles (Fig. 3 D, arrows; and Fig. S2, A and B) that are reminiscent of the contractile apparatus. In addition, α-actinin was associated with actin filaments that surround or overlap flat clathrin lattices (Fig. 3, E and G; and Fig. S2, A, C, and D) highly enriched with the adhesion marker β5 integrin (Fig. S2, E–H) as previously described on rat myotubes (De Deyne et al., 1998; Pumplin, 1989; Pumplin and Bloch, 1990), whereas vinculin was not localized at these clathrin-coated plaques (unpublished data).

Costameric clathrin forms large plaques where α-actinin and actin are localized

Myofibril assembly and subsequent sarcomere formation initiate at the PM. After the formation of a subcortical actin lattice, additional nascent sarcomeres keep adding to the initial actin network (Dlugosz et al., 1984; Epstein and Fischman, 1991; Sanger et al., 2002; Quach and Rando, 2006). We hypothesized that α-actinin and actin rely on a clathrin scaffold at the PM to start recruiting additional myofibrils and explored this possibility using immunogold cytochemistry coupled with quick-freeze, deep-etch rotary replication and electron microscopy (Heuser, 1980). We showed that clathrin forms two distinct coated structures, i.e., large plaques that contain much more polymerized clathrin that would be required to form a single vesicle (pseudocolored in red in Fig. 3, D and F) and coated vesicles found in regions devoid of plaques (Fig. 3, D and F; and Fig. S1, C–G). Using clathrin antibodies we were able to confirm that CHC was indeed the proteinaceous material composing these structures (Fig. S1, C–K). As expected, α-actinin strongly labeled dense longitudinally organized actin filament bundles (Fig. 3 D, arrows; and Fig. S2, A and B) that are reminiscent of the contractile apparatus. In addition, α-actinin was associated with actin filaments that surround or overlap flat clathrin lattices (Fig. 3, E and G; and Fig. S2, A, C, and D) highly enriched with the adhesion marker β5 integrin (Fig. S2, E–H) as previously described on rat myotubes (De Deyne et al., 1998; Pumplin, 1989; Pumplin and Bloch, 1990), whereas vinculin was not localized at these clathrin-coated plaques (unpublished data).
As expected, control myotubes present a striated $\alpha$-actinin distribution after 6 d of differentiation. This striated pattern is first visible at the periphery of the myotube and gradually fills the entire cytoplasm (Quach and Rando, 2006). In CHC-depleted myotubes, the $\alpha$-actinin striated pattern was strongly disrupted, and instead, clusters of $\alpha$-actinin were randomly dispersed in the intracellular space (Fig. 4 C). 3D projections of confocal sections confirmed a dramatic reduction of the striated pattern between controls and CHC-depleted myotubes (Fig. 4 D). Upon CHC depletion, a similar phenotype arises in mouse primary myotubes (Fig. 4, E and F) in which organization of actin filaments is also affected. To determine the role played by clathrin during the early steps of costamere formation, we performed siRNA depletion experiments on C2C12 myotubes after 4 d of differentiation, before $\alpha$-actinin and actin could reach a striated organization. In control myotubes, $\alpha$-actinin and actin were unaffected in myotubes treated with CHC siRNA (Fig. 4 A).

Our experiments on primary myotubes show that CHC forms large plaques that may serve to anchor the actin cytoskeleton and $\alpha$-actinin.

**CHC is required for the formation of costameres**

We next tested the effect of CHC knockdown on $\alpha$-actinin subcellular organization. We achieved high knockdown efficiency in C2C12 myotubes differentiated for 6 d (Fig. 4, A and B) with two previously published siRNA sequences (Ezratty et al., 2009). Additionally, we showed that levels of CLC were also reduced because of the instability of the light chain upon heavy chain depletion, as previously reported in nonmuscle cells (Brodsky, 1985; Esk et al., 2010). Expression levels of $\alpha$-actinin, vinculin, and talin were unaffected in myotubes treated with CHC siRNA (Fig. 4 A).

As expected, control myotubes present a striated $\alpha$-actinin distribution after 6 d of differentiation. This striated pattern is first visible at the periphery of the myotube and gradually fills the entire cytoplasm (Quach and Rando, 2006). In CHC-depleted myotubes, the $\alpha$-actinin striated pattern was strongly disrupted, and instead, clusters of $\alpha$-actinin were randomly dispersed in the intracellular space (Fig. 4 C). 3D projections of confocal sections confirmed a dramatic reduction of the striated pattern between controls and CHC-depleted myotubes (Fig. 4 D). Upon CHC depletion, a similar phenotype arises in mouse primary myotubes (Fig. 4, E and F) in which organization of actin filaments is also affected. To determine the role played by clathrin during the early steps of costamere formation, we performed siRNA depletion experiments on C2C12 myotubes after 4 d of differentiation, before $\alpha$-actinin and actin could reach a striated organization. In control myotubes, $\alpha$-actinin

Figure 4. CHC regulates formation and organization of sarcomeres in cultured myotubes. (A) Differentiated C2C12 cells were treated with control GAPDH siRNA, two different siRNA targeting CHC, a mixture of both (CHC-1, CHC-2, CHC-1+2 indicated at the top), and cell lysates immunoblotted for proteins (indicated at the right). (B) CHC expression in cultured C2C12 myotubes treated with GAPDH or CHC siRNA. The graph depicts quantification of CHC band intensity ($n = 8$ for CHC-1 and $n = 4$ for CHC-2 and CHC1+2; data are presented as mean ± SEM; **, $P < 0.01$). (C) $\alpha$-Actinin staining in differentiated C2C12 skeletal muscle cells treated with control GAPDH siRNA or CHC siRNA. The boxed region in the merged images is magnified in the insets. Bars: (main panels) 30 µm; (insets) 10 µm. (D) XZ and YZ projections of serial confocal sections. Bars, 10 µm. (E) CHC depletion on cultured primary mouse myotubes. Immunofluorescent staining of $\alpha$-actinin (green) and actin (red) in differentiated primary mouse myotubes treated with control GAPDH siRNA or CHC siRNA. DNA staining (DAPI blue) identifies multinucleated myotubes. The boxed region in the merged images is magnified in the insets. Bars: (main panels) 20 µm; (insets) 10 µm. (F) Quantification of striated vs. nonstriated surface in control (siRNA against GAPDH) or in myotubes treated with siRNA against CHC ($n = 30–60$ myotubes, data are presented as mean ± SEM; **, $P < 0.01$).
not due to perturbations of the secretory pathway or trafficking between the endo/lysosomal system.

DNM2 is also present at or near the plasma membrane of differentiating myotubes, where its staining partially overlaps with that of $\alpha$-actinin (Fig. S4 C). AP2 depletion strongly reduced the amount of DNM2 at the plasma membrane, suggesting that part of the PM staining corresponds to an association with clathrin lattices (Fig. S4 D). Efficient DNM2 depletion (Fig. S3 A) induced an increase in the amount of intracellular $\alpha$-actinin staining (Fig. 5 and Fig. S4 A). Of interest, these intracellular aggregates observed upon CHC, AP2, and DNM2 depletion also contain actin aggregates (Fig. S4 A).

We performed the quantification of the intracellular $\alpha$-actinin–positive area for all siRNA constructs (Fig. 5 B). CHC, AP2, and DNM2 had a strong impact on the intracellular $\alpha$-actinin area, whereas AP1 and AP3 values were not different from controls. Altogether, these results confirm that the primary impact observed upon CHC depletion on $\alpha$-actinin organization is not due to perturbations of the secretory pathway or trafficking between the endo/lysosomal system.

DNM2 is also present at or near the plasma membrane of differentiating myotubes, where its staining partially overlaps with that of $\alpha$-actinin (Fig. S4 C). AP2 depletion strongly reduced the amount of DNM2 at the plasma membrane, suggesting that part of the PM staining corresponds to an association with clathrin lattices (Fig. S4 D). Efficient DNM2 depletion (Fig. 5) induced an increase in the amount of intracellular $\alpha$-actinin staining (Fig. 5 and Fig. S4 A). Of interest, these intracellular aggregates observed upon CHC, AP2, and DNM2 depletion also contain actin aggregates (Fig. S4 A).

We performed the quantification of the intracellular $\alpha$-actinin–positive area for all siRNA constructs (Fig. 5 B). CHC, AP2, and DNM2 had a strong impact on the intracellular $\alpha$-actinin area, whereas AP1 and AP3 values were not different from controls. Altogether, these results confirm that the primary impact observed upon CHC depletion on $\alpha$-actinin organization is related to its cytoskeleton scaffolding role at the PM through a process also involving AP2 and DNM2.

Hip1R depletion stabilizes $\alpha$-actinin and actin on clathrin-coated structures

Actin has been shown to be present at CCVs (Collins et al., 2011), and a requirement for actin has been suggested for clathrin...
Hip1R-depleted myotubes accumulated unusual actin structures near the cell cortex (Fig. 6). These structures, which are very similar to the ones observed by Engqvist-Goldstein et al. (2004) upon Hip1R depletion in HeLa cells, took a variety of forms, including tails and rings at the bottom and the top of differentiated myotubes (Fig. 6 and Fig. S4 B). These results demonstrate that when Hip1R expression is reduced, actin polymerization at clathrin-coated structures is no longer properly regulated and results in accumulation of actin and α-actinin on clathrin-coated plaques.

**CHC is required for sarcomere maintenance in mature isolated muscle fibers**

We then assessed the function of CHC in mature skeletal muscle fibers. For this purpose, we developed an AAV strategy combined with the use of a short hairpin RNA (shRNA) against CHC (AAV-shCHC) for ex vivo transduction of isolated fibers.
In fibers depleted of CHC, the DNM2 signal at the core of the fiber was greatly reduced at the PM (Fig. 7 E). To assess the effect of CHC depletion on the integrity of the actin cytoskeleton we used phalloidin staining. In control fibers, F-actin displayed a regularly spaced striated distribution. However, CHC-depleted fibers presented a diffuse actin distribution (Fig. 7 F), and in some fibers detachment of entire sarcomeric bundles (Fig. 7 G). In addition to its role in costamerogenesis, these data suggest that CHC is also involved in their preservation in mature fibers.

Figure 7. CHC is required for sarcomere maintenance in adult fibers. (A) Quantitative RT-PCR and (B) Western blot analysis of CHC levels and proteins indicated at the right in FDB fibers infected with AAV-CTRL or AAV-shCHC for 12 d in vitro. (C) Quantification of Western blot CHC band intensity (n = 3, data are presented as mean ± SEM; for A and C: **, P < 0.01). (D–G) Confocal microscopy of dissociated FDB fibers infected with AAV-CTRL or AAV-shCHC for 12 d and co-stained with antibodies against either α-actinin and CHC (D), α-actinin and DNM2 (E), or F-actin (phalloidin staining) and caveolin-3 (F and G). All bars, 10 μm.

from flexor digitorum brevis (FDB) muscle. In AAV-shCHC–infected fibers, a strong decrease in CHC expression was confirmed, both at the RNA and protein level (Fig. 7, A–C), and α-actinin was no longer correctly localized, with very few striations noticeable and displaying a diffuse or disorganized staining pattern (Fig. 7 D). We also tested the effect of CHC depletion on DNM2 distribution. In control fibers, DNM2 displayed a striated pattern at the surface, with each striation being centered on the I-band, and in the core of the fiber DNM2 was mainly present at the PM (Durieux et al., 2010; Cowling et al., 2011). In fibers depleted of CHC, the DNM2 signal at the core of the fiber was greatly reduced at the PM (Fig. 7 E). To assess the effect of CHC depletion on the integrity of the actin cytoskeleton we used phalloidin staining. In control fibers, F-actin displayed a regularly spaced striated distribution. However, CHC-depleted fibers presented a diffuse actin distribution (Fig. 7 F), and in some fibers detachment of entire sarcomeric bundles (Fig. 7 G). In addition to its role in costamerogenesis, these data suggest that CHC is also involved in their preservation in mature fibers.
In vivo CHC depletion impairs force and causes muscle degeneration

We used AAV-shCHC in order to induce an in vivo depletion of CHC in tibialis anterior (TA) muscle. By performing hematoxylin and eosin staining on transverse TA sections (Fig. 8 A), no histological change was visible in muscles injected with control AAV or with AAV-shCHC until day 18 post-injection (PI). However, fibers displaying a rounded shape with a clearly disorganized intracellular space were noticed at day 21 PI. Between days 21 and 23 PI some degenerating fibers appeared, and by day 25 PI the vast majority of the fibers had a rounded shape with a clear degenerating phenotype. As a general feature of muscle degeneration, an immune infiltration was visible at day 21 and was extremely pronounced by days 23 and 25 PI. At day 25, small myotubes appeared and their presence reached a peak by day 38 where the majority of the muscle was centrally nucleated, the signature of a muscle undergoing massive regeneration.

Quantitative RT-PCR and Western blot analysis confirmed that at day 18 PI a strong decrease in CHC had indeed occurred (Fig. 8, B–D). When we measured CHC RNA and protein levels at later time points, we noticed that CHC levels increased from 40% back to 55% of control levels at day 21 PI and were back to control levels by day 23. Surprisingly, at day 25 PI, CHC levels were higher in the AAV-shCHC–injected muscle compared with the contralateral control muscle (Fig. 8, B and C). A possible explanation is that the infiltration by macrophages contaminates our analysis with exogenous clathrin from nontransduced immune cells. Indeed, at days 21, 23, and 25 PI a strong increase in CD11b protein levels was evident (Fig. 8 C and Fig. S5, A and B). Immunofluorescent staining confirmed that CD11b-positive macrophages had massively infiltrated the CHC-depleted muscle. In fact, CD11b protein levels correlated perfectly with the sudden increase in CHC levels. To circumvent the immune infiltration and to show that a clathrin knockdown had occurred, we performed immunoprecipitation experiments using antibodies against the muscle-specific α-actinin isoform. This assay enabled us to show that in muscles injected with AAV-shCHC, there was a strong decrease in the amount of CHC which immunoprecipitated with α-actinin (Fig. 8 E).

Direct muscle stimulation was performed in order to measure the maximal isometric strength of the TA muscle in CHC-depleted muscles. At day 18 PI, when no morphological alteration could be observed, CHC depletion induced a 57% decrease in specific maximal force, i.e., absolute maximal force divided by muscle weight (Fig. 8 F). At day 21 PI, CHC depletion had an even more robust effect; muscle depleted of CHC displayed a 74% decrease in specific maximal force (Fig. 8 F). No significant muscle mass loss was observed at both early timepoints (Fig. 8 G). These results show that AAV-shCHC efficiently knocks down CHC in vivo with dramatic consequences in terms of muscle fiber homeostasis.

In vivo CHC depletion perturbs α-actinin, γ-actin, and DNM2 distribution

We then sought to analyze the distribution of α-actinin, DNM2, and the costameric actin isoform γ-actin (Sonnemann et al., 2006) in CHC-depleted skeletal muscle by immunocytochemistry. At 18 d PI, the α-actinin labeling was not different from the control, whereas a clear reduction in sarcolemmal clathrin was apparent (Fig. 9 A). However, at day 21 and at further time points (day 23 and day 25), α-actinin and γ-actin both displayed a diffuse distribution compared with control muscle, and areas where α-actinin was no longer adjacent to the sarcolemma were also visible (Fig. 9, B–D). In addition, in control fibers DNM2 presented a strong PM staining and a weak intracellular staining. At day 21 and at further time points (day 23 and day 25) the DNM2 intracellular staining was greatly enhanced (Fig. 9, B and D). We also tested the effect of CHC depletion on the distribution of other costameric proteins such as dystrophin, β-dystroglycan, and caveolin-3 (Fig. S5, B and C). Even though at days 23 and 25 the muscle presented a severe dystrophic phenotype, no change in the distribution of these proteins was noticeable. We therefore conclude that CHC depletion has a strong effect on the localization of intracellular costameric proteins related to the actin cytoskeleton, including γ-actin, actin-associated proteins, and DNM2, without affecting the distribution of dystrophin and PM integral components such as members of the dystrophin-associated glycoprotein complex.

In vivo CHC depletion induces disorganization of the contractile apparatus and detachment between the sarcolemma and myofibrils

We performed electron microscopy analysis of CHC-depleted muscle at day 18 PI (without phenotype upon HE analysis) and at day 25 PI (peak of degeneration). At 18 PI focal regions displayed sarcomere abnormalities such as Z-band streaming and disorganization of the contractile apparatus especially in the I-band region (Fig. 10, A–C). It is of interest that these focal sarcomeric disorganizations were usually found adjoining the sarcolemma. In addition, at day 18 PI, occasional detachments of the sarcomeric apparatus from the sarcolemma were visible (Fig. 10, E–G). Both these phenotypes were consistent with the phenotypes produced upon clathrin depletion on isolated fibers. Of note, the T-tubule and sarcoplasmatic reticulum system did not seem affected in the disorganized regions (Fig. 10 D). At day 25 PI, both transverse (Fig. 10, H–J) and longitudinal sections (Fig. 10, K and L) presented a particularly exacerbated detachment phenotype, with fibers displaying large areas of the sarcolemma that were no longer associated with sub-sarcolemmal sarcomeres.

Discussion

In this study, we identify a new role for CHC in costamere formation and maintenance. Our results raise the possibility that CHC, AP2, and DNM2 contribute to the formation of the costameric scaffold that is necessary for anchoring the actin cytoskeleton by recruitment of actin-binding protein Hip1R and actin cross-linking protein α-actinin early during myotube differentiation. Consequently, depletion of CHC, by perturbing the actin cytoskeleton and redistributing α-actinin, has a strong effect on the formation and maintenance of the contractile
Figure 8. CHC depletion using AAV-shCHC in vivo impairs force and causes muscle degeneration. (C) CHC protein levels at different time points after AAV-CTRL or shCHC AAV injection. The full time-course of CD11b levels, including the D23 and D25 time points shown here, is shown in Fig. S5 A. (D) Quantification of Western blot CHC band intensity (n = 4 mice at day 18, data are presented as mean ± SEM; *, P < 0.05; Mann-Whitney U test). (E) Immunoblot analysis of proteins associated with α-actinin or control immunoprecipitates of TA muscle lysates injected with AAV expressing a control construct or AAV expressing shCHC at 21 d after injection. (F and G) Measures of the specific maximal force (F) and of the muscle weight (G) of isolated TA muscle injected with AAV expressing a control construct or AAV expressing the shCHC construct (n = 3–5 mice) at either 18 or 21 d after injection. Data are presented as means ± SEM; for F: *, P < 0.05; **, P < 0.01.
Clathrin heavy chain is required for sarcomere organization

Vassilopoulos et al.

cultured adipocytes (Bellve et al., 2006) and we observe them on non-adherent regions such as the top or the sides of myotubes (Fig. 2 D and Fig. S4 B). Because one putative role for clathrin-coated membrane domains is to maintain the stable attachment to the substrate, we suggest that clathrin plays the same role at the costamere, which is the muscle-specific adhesion site.

These large clathrin-coated plaques are also endocytically active, and invaginated pits are frequently observed at their edges. The implication of both CHC and DNM2 in focal adhesion turnover has previously been reported (Ezratty et al., 2005, 2009). Therefore, one may hypothesize that this protein complex responsible for formation and maintenance of the costameres is also involved in the turnover of these structures by endocytosis. In addition, we cannot exclude that the defects we are observing both in vitro and in vivo are at least partially due to defective endocytosis of costamere components. However, because (a) plaques in myotubes contain much more polymerized clathrin than would be required to form a single vesicle, (b) adhesion inhibits clathrin-mediated endocytosis (Batchelder and Yarar, 2010), and (c) endocytosis is reduced during differentiation (Kaisto et al., 1999), the defects we are observing in vitro and in vivo are at least partially due to defective endocytosis of costamere components.

The assembly of clathrin in plaques has been previously observed in several cell types, including muscle cells, but their physiological importance has proven controversial (De Deyne et al., 1998; Pumplin, 1989; Pumplin and Bloch, 1990; Akisaka et al., 2003; Bellve et al., 2006; Saffarian et al., 2009) and their functional role is still not clear. They were thought to represent artifacts of cell adhesion of cultured cells. However, large clathrin lattices have also been observed in non-adherent floating cultured adipocytes (Bellve et al., 2006) and we observe them on non-adherent regions such as the top or the sides of myotubes (Fig. 2 D and Fig. S4 B). Because one putative role for clathrin-coated membrane domains is to maintain the stable attachment to the substrate, we suggest that clathrin plays the same role at the costamere, which is the muscle-specific adhesion site.

These large clathrin-coated plaques are also endocytically active, and invaginated pits are frequently observed at their edges. The implication of both CHC and DNM2 in focal adhesion turnover has previously been reported (Ezratty et al., 2005, 2009). Therefore, one may hypothesize that this protein complex responsible for formation and maintenance of the costameres is also involved in the turnover of these structures by endocytosis. In addition, we cannot exclude that the defects we are observing both in vitro and in vivo are at least partially due to defective endocytosis of costamere components. However, because (a) plaques in myotubes contain much more polymerized clathrin than would be required to form a single vesicle, (b) adhesion inhibits clathrin-mediated endocytosis (Batchelder and Yarar, 2010), and (c) endocytosis is reduced during differentiation (Kaisto et al., 1999), the defects we are observing

Figure 9. α-Actinin, γ-actin, and DNM2 distribution is perturbed upon in vivo CHC depletion. (A–D) Confocal microscopy on transverse sections of skeletal muscle processed for double-immunofluorescent labeling using antibodies against (A) CHC (red) and α-actinin (green) at day 18 PI; (B) α-actinin (green) and DNM2 (red); (C) α-actinin (green) and DAPI (blue); (D) and γ-actin (green) and DNM2 (red) at day 21 PI. The boxed region in the merged images is magnified in the insets. Arrowheads point at regions of the fiber where the α-actinin staining is no longer associated with the sarcolemma. Bars: (main panels) 30 µm; (insets) 20 µm.
Figure 10. **Sarcomeric disorganization and detachment between sarcolemma and myofibrils upon in vivo CHC depletion.** Transmission electron microscopy of longitudinal (A–D, K–L) and transverse (E–J) muscle sections from mice injected with AAV-shCHC constructs at day 18 (A–G) and day 25 PI (H–L). In A–D, the sarcomeric apparatus is disorganized in focal regions adjoining the sarcolemma (within the dotted lines in A) and presents streaming and disassembly of the Z-line. C and D are insets of the respective boxed regions in B. In E–G, small detachments between the sarcolemma and the contractile apparatus are visible at day 18 PI. At day 25 PI, large detachments are seen in both transverse (H–J) and longitudinal orientation (K–L). I is an inset of the boxed region in H; J is an inset of the boxed region in I; L is an inset of the boxed region in K. Arrows in E, H, and L indicate detachments.
are probably not mainly due to endocytosis defects but could relate to the scaffolding role of CHC and DNM2 for the actin cytoskeleton (Schafer et al., 2002).

Our experiments show that these large clathrin-coated structures are intimately associated with the actin cytoskeleton and actin-binding proteins such as α-actinin. Because vinculin and talin were not detected in our coimmunoprecipitation experiments and because vinculin did not localize on clathrin-coated plaques (unpublished data), we believe that the coated domain corresponds to a different entity from classical focal adhesion contacts. The detection of clathrin plaques in situ in adult skeletal muscle is of great interest but remains technically challenging at the moment. It is of interest that costameres have been recurrently described as sub-sarcolemmal dense plaques (Chiesi et al., 1981; Pardo et al., 1983a;b; Shear and Bloch, 1985), and therefore it is tempting to speculate that part of the density which characterizes these structures could be attributed to clathrin plaques.

Early during in vivo clathrin depletion appear signs which point toward defects in costamere function. The first phenotype attributed to clathrin depletion is the presence of small detachments between the sarcolemma and the underlying myofibrils. CHC knockdown induces sarcomeric disorganization with streaming of the Z-line, which leads to a drastic and rapid muscle degeneration. Our in vivo experiments confirm the results obtained on differentiated myotubes and again point toward a role for CHC in the formation of stable plasma membrane compartments, which contributes to the attachment of sarcomeric lattices. Our results also point toward differences between three different costamere complexes. The first is centered on the DGC complex, dystrophin, ankyrins, and plectin (Ayalon et al., 2008; Randazzo et al., 2013), the second is centered on integrins, vinculin, α-actinin, and talin (Pardo et al., 1983a;b; Belkin et al., 1986), and the third is centered on integrins, α-actinin, and clathrin plaques (this paper); all three contain branched actin filaments. Also, the strong maximal force-loss seen in the clathrin-depleted muscle before any significant histological sign testifies to the vital role played by clathrin. The fact that more than 40% of the direct maximal force is lost before any change in total muscle mass or before the appearance of histological changes at the photon microscopy level could be attributed to the loss of both longitudinal and lateral force transmission in these myofibers. This force loss can be a direct consequence of both the large areas where disorganization of sarcomeres is evident and an uncoupling between the sarcolemma and the underlying contractile apparatus. Although the contribution of a trafficking dysfunction cannot be excluded, we believe that clathrin plays a structural role at the plasma membrane and that first appear signs related to this structural function.

Autosomal-dominant CNM is a rare neuromuscular disorder due to mutations in the DNM2 gene (Bitoun et al., 2005). The results reported here and previous data suggest that impairment of CHC and DNM2 function in the formation and maintenance of the contractile apparatus via costamere organization may be relevant in CNM pathophysiology. Similarly to clathrin, DNM2 is mainly localized at the PM and the Z-line, where it colocalizes with α-actinin in both mouse and human skeletal muscle (Cowling et al., 2011), and we show that DNM2 is required for proper α-actinin organization. Recently, a CNM-related DNM2 mutation was associated with an accumulation of electron-dense material located between disorganized myofibrils as well as DNM2 and CHC mislocalization within the atrophied myofiber (Kierdaszuk et al., 2013). In addition, overexpression of DNM2 mutants in mouse skeletal muscle leads to α-actinin structural defects with prominent misalignment of the Z-line in vivo, which may explain at least in part the reduced specific maximal force observed in these mice (Cowling et al., 2011). All these data associated with the undeniable role of DNM2 in regulation of actin cytoskeleton dynamics and focal adhesion maintenance (Ezratty et al., 2005, 2009) highlight a new putative pathomechanism of DNM2-related CNM that merits further investigation. Overall, our experiments clearly demonstrate the involvement of the CHC, the AP2 adaptor protein, Hip1R, and DNM2 in the formation of structures that, through association with α-actinin and actin filaments, allow the organization of the contractile apparatus in close association with the sarcolemma. The present study sheds light on a long-standing question, namely, the role of clathrin in skeletal muscle sarcomeric structure organization. Altogether, our results highlight an unconventional, novel role for clathrin in striated muscle that may be relevant to muscle physiology and whose dysfunction could be associated with the physiopathology of CNM linked to DNM2 mutations.

Materials and methods

Antibodies

Anti-CHC mouse monoclonals X22 and TD.1, rabbit polyclonal against clathrin light chains (anti-consensus), and mouse monoclonal AP6 (against α-subunit of AP2) used in this study were produced by Dr. Brodsky’s laboratory. The rabbit polyclonal antibody against CHC is from Abcam. For CHC detection in immunohistochemistry, immunocytochemistry, and electron microscopy we used the mouse monoclonal X22 antibody. The rabbit polyclonal was used for double-immunofluorescent labeling. Both X22 and the rabbit polyclonal anti-CHC completely colocalize. For Western blot experiments, both mouse monoclonal TD.1 and rabbit polyclonal [Abcam] antibodies were used. Other commercial sources of antibodies were as follows: mouse monoclonals against α-actinin 2, smooth-muscle actin, γ-actin, vinculin, and talin [Sigma-Aldrich]; mouse monoclonal SA4 against AP3-δ-subunit [DSHB]; rabbit polyclonal against AP1-γ-subunit; rabbit polyclonal anti-DNM2, rabbit polyclonal anti-integrin β5, rabbit polyclonal anti-GAPDH, and rabbit polyclonal anti-CDS1b [Abcam]; goat polyclonal anti-caveolin3 [Santa Cruz Biotechnology, Inc.]; rabbit polyclonal against dystrophin and mouse monoclonal against β-dystroglycan [Novocastra]; and rabbit polyclonal against Hip1R [EMD Millipore]. Secondary antibodies for immunofluorescence were from Life Technologies [Alexa Fluor 488, 568, and 633 conjugates]. Secondary antibodies coupled to horseradish peroxidase were from Jackson ImmunoResearch Laboratories, Inc.

Muscle tissue lysate

Lysates of whole tissue were prepared from freshly dissected mouse skeletal muscle. Tissue was homogenized by dounce in lysos buffer (1 mg/3 ml 50 mM Tris-HCl, pH 7.5, 0.15 M NaCl, 1 mM EDTA, 1% NP-40, and 1 protease inhibitor cocktail [1:10 ml buffer; Roche]). Homogenate was centrifuged for 10 min at 14,000 g, and the pellet discarded to obtain a post-nuclear supernatant. Protein concentration of the lysate was determined by Bradford assay [Bio-Rad Laboratories].

Immunoblot analysis

Protein samples were separated by electrophoresis (4–12% bis-acrylamide gel; Life Technologies), then electrophoretically transferred to 0.45-μm nitrocellulose membranes (Life Technologies) and labeled with primary antibodies and secondary antibodies coupled to horseradish peroxidase.
The presence of proteins in samples was detected using Western Lightning chemiluminescence reagent (GE Healthcare). Quantification was performed using Quantity One software (Bio-Rad Laboratories).

Subcellular fractionation
3T3 fibroblasts, C2C12 myoblasts, and differentiated C2C12 myotubes were homogenized in HES buffer at pH 7.4 (20 mM Hepes, 1 mM EDTA, and 225 mM sucrose) by passing 10x through a 27-gauge needle. Homogenates were centrifuged for 20 min at 19,000 g. The resulting pellets were resuspended in HES buffer, layered on top of a 1.2-M sucrose cushion and centrifuged at 101,000 g for 60 min at 4°C. The PM fraction was collected from the interface of the two solutions. Centrifugation of the initial supernatant (212,000 g) for 60 min at 4°C allowed separation of the intra-cellular membrane fraction (pellet) and cytosol (supernatant).

Immunoprecipitation
For 3T3 and C2C12 subcellular fractions (PM and cytosol), 250 µl of each fraction was diluted to half using lysis buffer (50 mM Tris-HCl, pH 7.5, 0.15 M NaCl, 1 mM EDTA, 1% NP-40, and 1 protease inhibitor cocktail tablet [1:10 ml buffer; Roche]). Mouse skeletal muscle tissue lysate (post-nuclear supernatant) was diluted to 3 mg/ml in lysis buffer, pre-cleared with 30 µl washed protein G-Sepharose (PGS 4 fast flow; GE Healthcare) per 400 µl of diluted lysate, and incubated with 20 µg of specific anti-subunit of the AP1 complex (manufacturer’s instructions). Targeting of GAPDH-specific control siRNAs were synthesized by Eurogentec. For CHC, sequences targeted were similar to those used in Ezraty et al. (2009): 5’-AACAUUGGCUCAUAGCUCCUUG-3’ for CHC-1, 5’-AAUGGUACUUCAUAGCUCCU-3’ for CHC-2, and 5’-GAGACUGUCCGACCGUGGC-3’ for CHC-3' for the ω-subunit of AP2. For the GAPDH siRNA sequence was 5’-AAUGGUACUUCAUAGGUACC-3’ and was used as a negative control in all siRNA experiments. The sequence of the siRNA for the γ-subunit of the AP1 complex (γ-adaptin) was 5’-AGCUAAUGAAGAUAAUUA-3’, which is similar to the sequence used in Dugast et al. (2005) and Braun et al. (2007). The sequence of the siRNA specific for the δ-subunit of the AP3 complex (δ-adaptin) was 5’-CAUCAUAGCUAUCGGCUG-3’, which is similar to the sequence used in Braun et al. (2007). The sequence of the siRNA specific for DM25 was 5’-ACCUAAUAGGUGGAGGAGGA-3’. The sequence of the siRNA specific for Hip1R was 5’-AACUCUCUGCA-CAGACGGUGA-3’, which is similar to the sequence used in Engevist-Goldstein et al. (2004). For CHC depletion, cells were transfected twice for 48 h. For all other siRNA constructs, cells were transfected once for 48–72 h.

Immunofluorescence microscopy
Adult mouse skeletal muscle was embedded in Tissue-Tek OCT compound (Miles, Inc.), frozen, and stored at −80°C. Cryosections (10-μm thick) were fixed (15 min, 4% paraformaldehyde in PBS or 10 min, 95% ethanol) at room temperature (RT), permeabilized (5 min, 0.5% Triton X-100 in PBS at RT), and blocked (30 min, PBS with 0.1% Triton X-100, 5% bovine serum albumin [BSA]). Sections were incubated with primary antibodies (overnight, 4°C, in PBS with 0.1% Triton X-100 and 5% BSA) and washed in PBS with 0.1% Triton X-100. Sections were then incubated with secondary antibodies (60 min at RT), washed in PBS with 0.1% Triton X-100, and mounted with anti-fading solution (DABCO) containing 300 nM DAPI. For double labeling, the two primary antibodies (from different species) or the two secondary antibodies were added simultaneously at the appropriate step. Secondary antibodies were labeled with either Alexa Fluor 488 or Alexa Fluor 568.

Muscle sections, mouse cells, and myofibers from mouse muscle were analyzed by confocal laser scanning microscopy using an inverted operating system (SP2; Leica) equipped with HCC Plan-Apo CS 40x/1.2 NA and 63x/1.40 NA oil immersion objective lenses. Images presented in Figs. 1A, 5, 6, S3, and S4 were acquired using an upright confocal laser scanning microscope (FV-1000; Olympus) equipped with a UPlanS- Apo 60x/1.35 NA oil immersion objective lens. DAPI, Alexa Fluor 488, and Alexa Fluor 568 fluorescence was sequentially excited using lasers with wavelengths of 405 for DAPI, 488 (Leica) or 473 (Olympus) for Alexa Fluor 488, and 543 nm for Alexa Fluor 568. Z-series from the top to the bottom of fibers were sequentially collected for each channel with a step of 0.9–1 μm between each frame. Imaging was performed at room temperature using Type F immersion oil (Leica). Images (1024 × 1024 pixels) were saved as TIFF files in Olympus FV-1000 software and Leica confocal software, and input levels were adjusted in Adobe Photoshop. Image quantification was performed using ImageJ (National Institutes of Health).

Image analysis
Striated surface measurement.

The α-actinin striated surface per myotube was quantified by manually drawing a region of interest in ImageJ around the striated or total cell surface in a single Z-stack from the middle of the cell. The striated surface was obtained by performing the ratio between striated and total myotube surface.

α-Actinin aggregate size analysis.
The “Analyze Particles” ImageJ plugin (version 1.46) was used to count intracellular particles on binary confocal images of C2C12 myotubes in a single Z-stack from the middle of the cell and to automatically measure the number and area of these particles.

shRNA constructs
The siRNA against CHC (CHC-1) used for in vitro transfection experiments was synthesized to be directly cloned in pSuper under the control of the H1 promoter. shRNA consisted of a 21-nt sense sequence followed by a 9-nt loop (ITCAAGAGA), a 19-nt reverse sequence, and an RNA pol III terminator (TTT). The H1 cassette was then introduced into an AAV1-based vector between the two ITRs using the blunted Spl and Sall sites on pSUPT/shRNA plasmid and the XbaI site on the pSMD2 AAV2 vector backbones, which were type I pseudotyped (Généthon).

Virus production and titration
AAV2/1 pseudotyped vectors were prepared by transfection in 293 cells as described previously (Riviere et al., 2006) using the pSMD2-shRNA plasmid, the pX06 plasmid (Généthon) coding for the adenoviral sequences essential for AAV production, and the pBlueCap plasmid (Généthon) coding for AAV1 capsid. Vector particles were purified on iodixanol gradients and concentrated on Amicon Ultra-15 100K columns (EMD Millipore). The final viral preparations were kept in PBS solution at −80°C. The particle titer (number of viral genomes) was determined by quantitative PCR. Titters for AAV shCHC were 4×1012 vector genomes (vg)/ml.

In vivo gene transfer
Experiments were performed on adult 8-wk-old C57/B6 mice. Anesthesia was achieved with a mix of 100 mg/kg ketamine and 10 mg/kg xylazine or using isoflurane. Two intramuscular injections (40 µl/TA), 24 h apart of AAV-shCHC, was performed in TA of the right hindlimb; the contralateral muscles were injected using the same procedure with control AAV vector (AAV-CTRL), which expresses the murine-secreted embryonic alkaline phosphatase (mSEAP). Mice were sacrificed at different intervals after the injection.
Gene expression analysis

Total RNA was prepared from 400-µm cryostat sections of TA using the NucleoSpin RNAII kit (Macherey-Nagel). Complementary DNA generated with the Superscript II Plus reverse transcription kit (Life Technologies) was analyzed by real-time qPCR performed on an Opticon2 system (Bio-Rad Laboratories) using iTaq SyberGreen Supermix with ROX (Bio-Rad Laboratories). In all samples, we quantified transcript of the PO gene encoding myosin acidic ribosomal phosphoprotein ubiquitously expressed as endogenous RNA control, and each sample was normalized on the basis of its PO content. Primers used for CHC: forward exon 6, 5′-GAGTCAAC-AGAAAGGGACA-3′; reverse exon 7, 5′-CATTCTCAAGGCAAACATTGAC-3′. Primers used for PO: forward, 5′-CTCAGAGTGAGTGACGACA-3′; reverse, 5′-ATAAGCTTGGCCGCATCGT-3′.

Histomorphological and ultrastructural analyses

Samples were frozen in liquid nitrogen-cooled isopentane. Transverse sections of TA muscle (8-µm thick) were stained with H&E by standard methods. Light microscopy was performed using an upright microscope (DMR; Leica) and a 40×/0.85 HCX Plan Apo objective (Leica). Images were captured using a monochrome camera (DS-Ri1; Nikon) and NIS-Elements BR software (Nikon). For all imaging, exposure settings were identical between compared samples and viewed at room temperature.

For morphological electron microscopy, muscles were fixed by intracardiac perfusion with 2% paraformaldehyde and 2% glutaraldehyde in 0.1 M phosphate buffer (pH 7.4). TA samples were postfixed with 2% OsO4 in 0.1 M phosphate buffer (pH 7.4) for 1 h, then dehydrated in a graded series of acetone containing 1% uranyl acetate staining step in 70% acetone and finally embedded in epoxy resin. For pre-embedding immunogold clathrin labeling, mice were fixed with 2% paraformaldehyde and TA longitudinal 100-µm-thick sections were cut with a vibratome. Then a standard free-floating immunocytochemical procedure was followed, using 0.1 M saline phosphate buffer as diluent and rinsing liquids. After pre-incubation in 5% normal goat serum, 5% BSA, sections were incubated overnight at 4°C in 1:500 anti-clathrin antibody. A further 4-h incubation in ultra-small gold conjugate of goat anti-rabbit IgG (1:20; Auroin) was followed by extensive washings, 10 min post-fixation in 2% glutaraldehyde, and 0.70-nm gold beads were then silver enhanced (HQ silver; Nanoprobes). After 15 min post-fixation in 1% OsO4, sections were dehydrated in graded acetone and embedded in epoxy resin.

Thin (70 nm) sections were stained with uranyl acetate and lead citrate, and in some cases (Fig. 1 F) a 1% tannic acid (1 min) staining step preceded uranyl staining. Observations were made on an electron microscope (model CM12; Philips) and images were recorded with a Morada digital camera (Olympus).

Electron microscopy of unroofed myotubes

Adherent PM from myotubes cultured as described above were prepared for rapid-freeze, deep-etch electron microscopy as described previously (Heuser, 2000). In brief, cells grown on small oriented pieces of glass coverslips were disrupted by sonication, fixed in paraformaldehyde, and labeled with anti-clathrin (K22), anti-α-actinin, or anti-β5 integrin and then 18-nm gold-conjugated anti-mouse or anti-rabbit antibody. Each water-washed coverslip is mounted on a 3 × 3-mm slab of aldehyde-fixed and water-washed rabbit lung (0.8-mm thick) that serves as a cushion for the samples and viewed at room temperature.

For rapid-freeze, deep-etch electron microscopy as described previously (Bitoun et al., 2010). Differential requirements for clathrin-dependent endocytosis at sites of cell-substrate adhesion. Mol. Biol. Cell. 21:3070–3079. http://dx.doi.org/10.1091/mbc.E09-12-1044

Figure S1. **Ultrastructural localization of clathrin in adult skeletal muscle and mouse primary myotubes.** (A) Thin (70 nm) longitudinal muscle sections were stained with 1% tannic acid followed by uranyl acetate and lead citrate. An arrow points at electron-dense regions corresponding to costameres. Z-line position is indicated by letter Z. (B) Thin longitudinal muscle sections immunolabeled with CHC polyclonal antibody and processed for EM. (C–K) Fixed PM sheets prepared from control primary myotubes were labeled with CHC antibodies, and then with secondary antibodies conjugated to 18-nm colloidal gold particles. Representative freeze-etch images show the distribution of clathrin on small, flat, or invaginated coated pits (C–G) or on large, flat, actin-associated coated plaques (H–K). Bars, 100 nm.
Figure S2. Additional images of α-actinin localization and localization of β5-integrin in clathrin plaques. (A–D) Adherent plasmalemmal sheets prepared from control primary mouse myotubes were labeled with α-actinin antibodies followed by secondary antibodies conjugated to 18-nm colloidal gold particles (pseudocolored yellow). Note that α-actinin is found on both the contractile apparatus (A and B) and on large and flat clathrin-coated lattices (A, C, and D). (E–H) Fixed PM sheets prepared from control myotubes were labeled with β5-integrin antibodies, and then with secondary antibodies conjugated to 18-nm colloidal gold particles. Representative freeze-etch images show the spatial distribution of endogenous β5-integrin enriched on large clathrin-coated structures. In A, E, and G, clathrin lattices are pseudocolored pale red.
Clathrin heavy chain is required for sarcomere organization

Figure S3. siRNA-mediated depletion of AP1, AP2, AP3, DNM2, and Hip1R. (A) Differentiated C2C12 myotubes were treated with either siRNA targeting GAPDH, the γ-subunit of AP1, the α-subunit of AP2, the δ-subunit of AP3, DNM2, or Hip1R. Immunofluorescent staining (DNA staining with DAPI is shown in blue (bar, 10 µm) and the boxed region in the merged images is magnified in the insets (bar, 5 µm). (B) Differentiated C2C12 myotubes were treated with either siRNA targeting GAPDH, the γ-subunit of AP1, the α-subunit of AP2, the δ-subunit of AP3, DNM2, or Hip1R and subjected to Western blot detection of the γ-subunit of AP1, the α-subunit of AP2, the δ-subunit of AP3, DNM2, or Hip1R. (C) Differentiated C2C12 skeletal muscle cells were treated with control GAPDH siRNA or siRNA against AP2 and processed for immunofluorescent staining with antibodies against the α-subunit of AP2 (green) and CHC (red). DNA staining (DAPI, blue) identifies differentiated, multinucleated myotubes (bar, 10 µm). The boxed region in the merged images is magnified in the insets (bar, 10 µm). (D) Differentiated C2C12 myotubes were treated with either siRNA targeting GAPDH, CHC, or the α-subunit of AP2 and processed for immunofluorescent staining with antibodies against the α-subunit of AP2 (green) and Hip1R (red). DNA staining (DAPI, blue) identifies differentiated, multinucleated myotubes (bar, 10 µm). The boxed region in the merged images is magnified in the insets, and arrows in C and D indicate colocalization between AP2 and CHC or AP2 and Hip1R, respectively (bar, 5 µm).
Figure S4. **Effect of siRNA-mediated depletion of CHC, AP1, AP2, Hip1R, and DNM2 on actin distribution and localization of DNM2 in control and AP2-depleted C2C12 myotubes.** (A) Differentiated C2C12 myotubes were treated with either siRNA targeting GAPDH, CHC, the γ-subunit of AP1, the α-subunit of AP2, or DNM2 and processed for immunofluorescent staining with antibodies against α-actinin (green) and treated with TRITC-phalloidin in order to label actin filaments (red). DNA staining (DAPI, blue) identifies differentiated, multinucleated myotubes. The boxed region in the merged image is magnified in the inset. (B) Differentiated C2C12 myotubes were treated with either siRNA targeting GAPDH or Hip1R and processed for immunofluorescent staining with FITC-phalloidin (green) in order to label actin filaments and antibodies against CHC (red). Bar, 10 µm. XZ and YZ projections of serial confocal sections are shown for each individual channel and the overlay image (B, bottom; T, top). The boxed region in the overlay is magnified in the insets (bar, 5 µm). Arrows indicate colocalization between actin filaments and CHC. (C) Immunofluorescent staining of α-actinin (green) and DNM2 (red) in differentiated C2C12 myotubes treated with siRNA targeting GAPDH. DNA staining (DAPI, blue) identifies differentiated, multinucleated myotubes. The boxed region in the merged image is magnified in the inset. A black and white composite image depicting colocalized pixels between the α-actinin and DNM2 staining is shown. (D) Differentiated C2C12 myotubes were treated with either siRNA targeting GAPDH or the α-subunit of AP2 and processed for immunofluorescent staining with antibodies against the α-subunit of AP2 (green) and DNM2 (red). DNA staining (DAPI, blue) identifies differentiated, multinucleated myotubes. The boxed region in the merged images is magnified in the insets.
Figure S5. **CHC depletion induces a strong inflammatory response and has no effect on β-dystroglycan and dystrophin distribution.** (A) Western blot analysis of CD11b protein levels at 18, 19, 23, or 25 d after AAV-CTRL or AAV-shCHC injection. The D23 and D25 time points of this Western blot were previously shown in Fig. 8 C. GAPDH serves as a loading control. (B) Confocal microscopy on transverse sections of skeletal muscle processed for double-immunofluorescent labeling using antibodies against CD11b (red) and caveolin-3 (green, used as a marker to delineate muscle fibers) at day 18, 21, 23, and 25 PI. The overlay shows these images overlapped in color and in addition contains the DNA staining (DAPI, blue). (C) Confocal microscopy on transverse sections of skeletal muscle processed for double-immunofluorescent labeling using antibodies against β-dystroglycan (green) and dystrophin (red) at day 21 and 23 PI.
