Male reproductive glands secrete signals into seminal fluid to facilitate reproductive success. In *Drosophila melanogaster*, these signals are generated by a variety of seminal peptides, many produced by the accessory glands (AGs). One epithelial cell type in the adult male AGs, the secondary cell (SC), grows selectively in response to bone morphogenetic protein (BMP) signaling. This signaling is involved in blocking the rapid remating of mated females, which contributes to the reproductive advantage of the first male to mate. In this paper, we show that SCs secrete exosomes, membrane-bound vesicles generated inside late endosomal multivesicular bodies (MVBs). After mating, exosomes fuse with sperm (as also seen in vitro for human prostate-derived exosomes and sperm) and interact with female reproductive tract epithelia. Exosome release was required to inhibit female remating behavior, suggesting that exosomes are downstream effectors of BMP signaling. Indeed, when BMP signaling was reduced in SCs, vesicles were still formed in MVBs but not secreted as exosomes. These results demonstrate a new function for the MVB–exosome pathway in the reproductive tract that appears to be conserved across evolution.

**Introduction**

In addition to sperm, seminal fluid contains multiple factors secreted by male reproductive glands that activate sperm (Rodríguez-Martínez et al., 2011) and can influence female physiology and behavior (Kershaw-Young et al., 2012). In *Drosophila melanogaster*, the paired accessory glands (AGs) secrete peptides that perform such functions (Wolfner, 1997). Sex peptide (SP) is one key product that in females can induce enhanced egg laying (Chapman et al., 2003), gradual release of sperm from storage organs (Liu and Kubli, 2003; Peng et al., 2005; Avila et al., 2010), and reduced receptivity to remating (Chen et al., 1988). This latter effect directly conflicts with unknown mechanism.

Exosomes are secreted membrane-bound, nanosized (40–100 nm) vesicles generated in late endosomal multivesicular bodies (MVBs; Raposo and Stoorvogel, 2013; Christianson et al., 2014). They are thought to mediate short- and long-range intercellular signaling events in biological contexts, such as immune (Théry et al., 2009) and tumor cell signaling (Ge et al., 2014). They are distributed under the terms of an Attribution–Noncommercial–Share Alike–No Mirror Sites license for the first six months after the publication date (see http://www.rupress.org/terms). After six months it is available under a Creative Commons License (Attribution–Noncommercial–Share Alike 3.0 Unported license, as described at http://creativecommons.org/licenses/by-nc-sa/3.0/).
Exosomes can carry ligands, receptors, intracellular signaling molecules, lipids, and nucleic acids, allowing them to participate in a wide range of functions at the cell surface or when their contents are discharged into target cells through fusion or endocytosis (Raposo and Stoorvogel, 2013; Christianson et al., 2014). They are probably secreted into the extracellular milieu by all cells and enter body fluids, such as plasma and urine (Nilsson et al., 2009; Lance et al., 2011; Properzi et al., 2013; Record et al., 2014).

Prostate-derived exosomes (or prostasomes) have reported functions in healthy and tumorigenic prostate (Ronquist, 2012; Soekmadji et al., 2013). In vitro studies suggest roles for prostasomes and epididymis-derived exosomes (epididymosomes) in promoting motility during sperm capacitation (Palmerini et al., 1999; Park et al., 2011; Aalberts et al., 2013) and maturation (Sullivan and Saéz, 2013), respectively. In these ex vivo experiments, prostasomes fuse specifically to the head/neck region of sperm, potentially under pH control (Arienti et al., 1997; Park et. al., 2011; Aalberts et al., 2013).

Here, we demonstrate that SCs of the AG secrete exosomes in vivo. The very large size of SC endolysosomal compartments allows aspects of exosome biogenesis to be visualized in living tissue for the first time, revealing remarkably dynamic membrane deformation and fusion events. Secreted exosomes fuse with sperm in vivo in females after mating, phenocopying reported properties of human prostasomes in vitro (Arienti et al., 1997; Park et al., 2011). Furthermore, SC-derived exosomes interact with epithelial cells in the female reproductive tract and are required to induce changes in female remating behavior controlled by BMP signaling. Secretion, but not formation, of SC-derived exosomes requires BMP signaling, highlighting endolysosomal trafficking as a key regulator of SC function. Thus, regulated secretion of exosomes in the AG provides an essential part of the armory promoting male-specific interests during Drosophila reproduction.

Results

SCs secrete CD63-GFP-marked puncta into the AG lumen

Each AG secretes into a large lumen, which opens at its proximal end into the ejaculatory duct (Fig. 1, A–C). We expressed a GFP-tagged tetraspanin, CD63, a mammalian transmembrane exosome marker used previously to mark fly exosomes (Panáková et al., 2005; Gross, et al., 2012), independently in MCs and SCs (Figs. 1, A–C; and S1, A and B) using the GAL4/upstream activating sequence (UAS) system (Brand and Perrimon, 1993). In SCs of 3-d-old males, CD63-GFP localized to the limiting membrane of all large (>2-µm diameter) vacuoles and, in some cells, to the apical plasma membrane (Fig. 1 F). Not all vacuoles were identical, however; the majority appeared to be compartments previously described as secretory vacuoles (SVs; Rylett et al., 2007) because they had a dense core containing the secreted protease angiotensin-converting enzyme I (ANCE; Fig. 1, E and F). CD63-GFP–positive puncta, presumably representing intraluminal vesicles (ILVs), were also observed inside many vacuoles, especially in live specimens.

These puncta were typically most prominent in at least one acidic compartment, stained with the vital acid-sensitive dye LysoTracker red (Fig. 1, G and H).

The AG lumen contained GFP-marked puncta (Figs. 1, C and D; and S1, A and F), which were not observed when CD63-GFP was expressed in the large number of MCs in the AG (Fig. S1 B), suggesting that only SCs secrete this tagged membrane protein. Overexpressed cytoplasmic GFP was sometimes incorporated into puncta inside SC vacuoles (Fig. S1 C), indicating that the puncta are not induced by CD63-GFP expression. Furthermore, another tagged, nonexosomal membrane protein, CD8-RFP, which labels all vacuolar compartments and is internalized in some of them, was not secreted (Fig. S1, D and E), suggesting that CD63-GFP is packaged into intraluminal structures and selectively secreted. In support of this, luminal vesicles ~40 nm in diameter, as well as other particulate material, were observed by transmission EM in the AG lumen of wild-type males (Fig. S2 G).

CD63-GFP-positive puncta are located inside late endosomes and lysosomes

We analyzed the large SC compartments in more detail using LysoTracker red–stained living glands. Counting vacuoles by scanning through multiple focal planes revealed remarkably consistent numbers of large (>2 µm) and small (<2 µm) CD63-positive acidic compartments and large nonacidic CD63-positive compartments in each SC of 6-d-old adults (Fig. 1 I). Both classes of acidic compartments were also visible in non–CD63-GFP–expressing SCs (Figs. S1, G versus H; and 2, A–C) and therefore were not induced by CD63-GFP expression. We hypothesized that the smaller apical acidic compartments were immature late endosomes (iLEs; CD63-GFP+/LysoTracker+ and <2 µm; Fig. 1 I), and the large acidic compartments, at least one of which contained small CD63-GFP–positive puncta, were unusually large (≤10 µm in 6-d-old SCs) maturing MVBs or lysosomes (mMVBs; CD63-GFP+/LysoTracker+ and >2 µm; Fig. 1 I). In addition, some, but not all, nonacidic SV compartments (CD63-GFP+/LysoTracker− and >2 µm; Fig. 1 I) contained larger CD63-GFP–positive intraluminal structures.

In each SC, an anti-CD63 antibody, which cross-reacted with fluorescent GFP puncta in the AG lumen (Fig. S2, B and C), also stained most of the lumen of either one or two compartments, which contained only sporadic fluorescent GFP puncta (Fig. S2 A). These compartments were ANCE negative and therefore not SVs. We reasoned that they were acidic compartments in which the microenvironment must partially inhibit fluorescence of internalized GFP. To confirm that SCs have giant vesicle-containing compartments, we analyzed SC ultrastructure by transmission EM (Fig. S2, E–I). In addition to the SV compartments previously reported by Rylett et al. (2007), SCs possessed one or two less electron-dense compartments containing vesicles ~40 nm in diameter, an appropriate size to be precursors of secreted exosomes (Fig. S2 I). The ultrastructure of these large compartments was difficult to preserve in fixed, sectioned material, but because they are not filament- and ANCE core-containing SVs, we conclude that they must represent the acidic vesicle-containing compartments we observe in live specimens.
We performed more detailed live-imaging analysis of these large acidic and nonacidic SC compartments to confirm their identity, using selected ubiquitously expressed YFP-tagged Rab GTPases (Marois et al., 2006) that regulate endocytic trafficking and exosome secretion (Savina et al., 2002; Fader et al., 2005; Stenmark, 2009; Koles et al., 2012; Beckett et al., 2013). SCs typically contained two or three large vacuoles lined with Rab7-YFP, most of which were acidic (Fig. 2 A). Importantly, because all large acidic compartments were Rab7 positive (n > 50 cells), this confirms that the acidic compartments with CD63-GFP–positive puncta are either MVBs or lysosomes containing undegraded GFP. In support of this, these large acidic compartments were also lined by a GFP fusion with type II phosphatidylinositol kinase (PI4KII-GFP; Fig. S2 D), which marks late endosomes and lysosomes in other Drosophila secretory cells (Burgess et al., 2012).

Rab11-YFP, a marker for exocytic and recycling endocytic membranes, which regulates exosome secretion in flies (Chen et al., 1998; Koles et al., 2012; Beckett et al., 2013), localized to the limiting membrane of nonacidic SVs (Fig. 2 B). However, expression of this marker induced loss of large mMVBLs in most SCs (10/13 cells); overexpression of wild-type Rab11 therefore

Figure 1. SCs secrete CD63-GFP–positive, exosome-like puncta. (A–D) Paired accessory glands (AG) expressing CD63-GFP in SCs connect to the ejaculatory duct (ED; A). Images of different magnifications show surface sections of SCs within the AG epithelium [B, from square in A, arrows mark two SCs], a transverse section through the lumen [C; bracketed region in B, arrows mark two SCs], and CD63-GFP-positive puncta in the lumen [D; square in C; an image at higher confocal gain setting is shown in Fig. S1 F]. (E and F) High magnification images of surface [E] and transverse [F; asterisk marks the lumen containing GFP puncta] sections through the SC show that CD63-GFP is also found at the apical plasma membrane [arrowhead; F] and the limiting membrane of SC vacuoles, the majority of which have a dense ANCE-positive core [highlighted with arrows]. One or two CD63-GFP–lined compartments per SC lack an ANCE-stained core but contain fluorescent puncta [E, asterisk]. Fasciclin3 (Fas3) marks septate junctions at the cell surface, and DAPI marks nuclei [note that SCs and MCs are binucleate]. (G and H) Vital staining of SCs with LysoTracker red reveals CD63-GFP–positive puncta (putative ILVs; arrows) in large acidic compartments (mMVBLs), distinguishing them from other compartment classes, such as the more abundant secretory vacuoles (SVs) and immature late endosomes (iLEs). All images show SCs from 3-d-old males incubated at 28.5°C after eclosion. (I) Schematic representation of compartments within SC in H; values below indicate the mean total numbers of each compartment in 6-d-old control SCs counted from multiple sections along the apical–basal axis; the numbers of SCs analyzed are given in brackets. Approximate outline of the SC is marked in E–H. Bars: (A and B) 200 nm; (C) 20 µm; (D–H) 5 µm.
with iLEs. In support of this, we found Rab7 colocalizes with Rab11-YFP at the limiting membrane of a subpopulation of Rab11-YFP–lined SVs (Fig. 2 D). In conclusion, SCs contain unusually large secretory and acidic vacuoles, permitting the in vivo analysis of these compartments at high spatial resolution. At least one large acidic compartment in each SC contains CD63-positive puncta (Fig. 1, G and H), and equivalent large vesicle–containing structures are also observed by EM (Fig. S2).

Figure 2. **Rab GTPase signatures define different SC subcellular compartments.** (A–D) SCs from 3-d-old males expressing different Rab-YFP constructs and stained with LysoTracker red. SCs have 5–10 small acidic Rab7-YFP–positive iLEs (A, arrowheads; most of these are usually located more apically than this confocal section; see Fig. 3) and 2.4 ± 0.9 (n = 11) Rab7-YFP–positive large vacuoles, 85% of which are acidic mMVBLs (A, asterisks; similar numbers [2.9 ± 0.5, n = 9] of large acidic compartments are seen in CD63-GFP–expressing SCs at this stage). Other Rab-YFP lines reveal Rab11-YFP–positive, nonacidic SVs (B, +; and D), many Rab5-YFP–positive small nonacidic compartments (C, arrowheads), and more rarely (4/16 SCs), a Rab5-YFP–positive small acidic compartment (C, arrows). In some fixed tub>Rab11-YFP SCs stained for Rab7, Rab7 colocalizes with Rab11-YFP in parts of the limiting membrane (D, arrow) of a single SV (D, #). DAPI stains nuclei (blue). Approximate outline of SC is marked in all images. Bars, 5 µm.

alters trafficking to mMVBLs, as has been found in other systems (Savina et al., 2002, 2005). Finally, Rab5-YFP, a marker for early endosomes, mainly localized to many small (<2 µm) nonacidic, centrally clustered compartments, often in close proximity to iLEs (Fig. 2 C). Interestingly, large nonacidic Rab7-YFP–positive vacuoles were typically in contact with acidic Rab7-YFP–positive iLEs (Fig. 2 A), consistent with a model in which the former compartments might derive from Rab11-positive vacuoles by fusion with iLEs. In support of this, we found Rab7 colocalizes with Rab11-YFP at the limiting membrane of a subpopulation of Rab11-YFP–lined SVs (Fig. 2 D). In conclusion, SCs contain unusually large secretory and acidic vacuoles, permitting the in vivo analysis of these compartments at high spatial resolution. At least one large acidic compartment in each SC contains CD63-positive puncta (Fig. 1, G and H), and equivalent large vesicle–containing structures are also observed by EM (Fig. S2).
Strikingly, real-time confocal imaging of SCs revealed nonacidic SVs fusing with mMVBLs and rapid exchange of limiting membrane components (Fig. 4 A and Video 1). Although the internal contents of these compartments did not mix freely, these findings suggest a surprising level of exchange between SVs and mMVBLs and might explain how CD63-GFP–positive structures accumulate in SVs (Fig. 1, E–H).

Endolysosomal and secretory compartments in SCs are highly dynamic

We followed CD63-GFP trafficking through the secretory and endolysosomal systems using a pulse–chase approach. Induction of a short (8 h) pulse of CD63-GFP expression, by inhibiting the temperature-sensitive GAL4 transcriptional repressor GAL80ts at 28.5°C, followed by a chase period at 18°C of 0–60 h, revealed rapid labeling of two (1.9 ± 0.2, n = 17) nonacidic SVs, presumably receiving newly synthesized CD63-GFP from the Golgi (Figs. 3, A and B; and S3, A and B). Some iLEs were also GFP positive immediately after the pulse. During the early part of the time course, a greater proportion of SCs contained labeled iLEs than labeled mMVBLs (P = 0.001, n > 27), and this trend continued at later time points (Figs. 3, A–G; and S3, A–F), supporting our model in which CD63-GFP traffics first to the iLEs and subsequently to mMVBLs.
upon mating (Fig. 5 K), consistent with the reduced secretion of this exosome marker. An alternative explanation for these results is that ESCRT knockdown affects all secretion by SCs. However, the SC-specific production (Rylett et al., 2007) of the secreted, nonexosomal protease ANCE (Figs. 5 J and S4, B–D), its secretion into the AG lumen (Fig. S4, E–G), and its transfer into females (Fig. 5 K) were not affected by ALix or Hrs knockdown, showing that these treatments selectively affect the exosome biogenesis pathway in SCs.

To provide further evidence that SCs produce CD63-positive exosomes, we modulated the activities of three Rabs previously implicated in exosome secretion: Rab11 (Savina et al., 2002; Koles et al., 2012; Beckett et al., 2013), Rab35 (Hsu et al., 2010), and Rab27 (Ostrowski et al., 2010). Expression of dominant-negative Rab11-YFP (Rab11DN; Zhang et al., 2007), Rab11-RNAi, Rab35-RNAi, and one of two Rab27-RNAi’s significantly reduced the number of secreted GFP-positive puncta (Figs. 5 A and S5, A and B). Previous studies have indicated that Rab35 and Rab27 do not regulate secretion of exosomes carrying the cargo receptor Evenness Interrupted (Evi) in Drosophila S2 cells (Koles et al., 2012; Beckett et al., 2013), suggesting multiple exosome secretion routes in flies as well as mammals. Indeed, expression of two different RNAi’s targeting Evi, which is required to produce Wingless-containing exosomes (Beckett et al., 2013) but is not required for CD63-GFP-positive exosome secretion in flies (Gross et al., 2012), did not affect the number of secreted puncta in the gland lumen (Fig. 5 A). Finally, the number of secreted puncta was also significantly reduced when Rab7-RNAi or dominant-negative Rab7-YFP (Rab7DN; Zhang et al., 2007) was expressed in SCs (Fig. 5 A), implicating late endolysosomal trafficking events in secretion. Based on these extensive genetic data,
Figure 5. ESCRTs, Rab GTPases, and BMP signaling regulate the exosome biogenesis pathway. (A) The numbers of CD63-GFP-positive puncta secreted into the AG lumen were significantly reduced in SC>Hrs-RNAi, SC>ALiX-RNAi, SC>Rab11DN, SC>Rab11-RNAi, SC>Dad, SC>Rab7-DN, SC>Rab7-RNAi, SC>Rab27-RNAi, and SC>Rab35-RNAi males compared with control (number of glands above or in the bars) but not SC>Rab27-RNAi2 and
we conclude that SCs secrete CD63-GFP–positive exosomes whose biogenesis and secretion are regulated by evolutionarily conserved molecular mechanisms.

Interestingly, despite the large number of CD63-GFP–positive exosomes in the AG lumen, they did not seem to fuse with MCs in most of the gland (Fig. S5 C). However, we did observe occasional GFP puncta inside MC neighbors of SCs at the distal tip of each AG (Fig. S5 D). The regionalized nature of this uptake indicates that it may be mediated by contact-dependent transfer between SCs and MCs, rather than transfer via the AG lumen.

**SC exosomes fuse with sperm and interact with epithelial cells in the female reproductive tract**

We investigated whether the interaction between SC exosomes and target cells primarily takes place after mating. *SC>CD63-GFP* males transferred fluorescent puncta into the lumen of the female reproductive tract during mating (Fig. 6, A–D). Multiply mated males of 11 d and older can sporadically transfer SCs to females (Leiblich et al., 2012). Importantly, all mating experiments performed in our current study were with 4-d-old males; we never observed transfer of fluorescent SCs in >50 mated females that we imaged, indicating that SC transfer is not involved in the phenotypes observed.

Several seminal peptides target specific regions of the female reproductive tract and/or sperm after mating (Peng et al., 2005; Ravi Ram et al., 2005). Isolated human prostasomes fuse with the sperm midpiece in vitro, delivering Ca²⁺ signaling molecules implicated in sperm motility (Fabiani et al., 1994; Park et al., 2011). We also detected colocalization of CD63-GFP and sperm heads in the female reproductive tract after mating (Fig. 6, D and E). Analysis of confocal z series images revealed narrow rings of GFP surrounding the sperm head (Fig. 6 F), as might be expected after exosome–sperm fusion. These events were most commonly observed at 20 min after the start of mating (88% [14/16] mated females; Fig. 6 H) in the anterior portion of the female reproductive tract where sperm and exosomes accumulated, either in the anterior uterus (9/16) or the oviduct (5/16). This fusion frequency is almost certainly underestimated: first, because CD63-GFP is likely to rapidly diffuse and dissipate over the sperm surface after fusion, so the GFP fluorescence signal will rapidly become undetectable, and second, because there may be additional fusion to sperm tails. Although tools were not available to fluorescently colabel exosomes and sperm tails, pairs of short parallel fluorescent lines or extended irregular lines of GFP fluorescence were always seen in the female reproductive tract lumen (100%, n = 8; Fig. 6, F and G; and Video 3), which might represent such events. We did not observe CD63-GFP in sperm storage organs, though as discussed previously in this paper, GFP may dissipate after fusion to sperm before entering these structures.

Interestingly, we noted accumulation of CD63-GFP exosomes at the surface of the reproductive tract either in the uterus or oviduct in 40% of females (Fig. 7; n = 34), suggesting that SC exosomes also interact with female epithelial cells. In some cases, fluorescent aggregates made contact with the epithelium (Fig. 7 C and Video 4), whereas in others, dispersed puncta aligned along the epithelial surface (Fig. 7 D). These interactions may reflect docking to female cell targets, either before internalization via endocytosis (Morelli et al., 2004) or possibly as part of a cell surface signaling mechanism. In summary, SC-derived exosomes do not seem to fuse to the AG epithelium in virgin males but do fuse to sperm and interact with female epithelial cells after mating.

**SC exosomes modulate female receptivity to remating**

In contrast to virgin females, recently mated *Drosophila* females will reject a courting male (Wolfner, 1997). We have previously shown that BMP signaling in SCs is required for full induction of this female remating behavior (Leiblich et al., 2012). We hypothesized that SC-derived exosomes might be involved in this function. Remarkably, blocking exosome production, using SC-specific expression of either ALIX-RNAi or dominant-negative Rab11, reduced the ability of males to prevent female remating (Fig. 8 A). Importantly, and similar to our observations when BMP signaling is blocked in SCs (Leiblich et al., 2012), we did not see any significant effect on egg laying, fecundity, or mating behavior for *SC>ALIX-RNAi* males (mating times, but not egg laying or fecundity, were reduced for *Rab11DN*; Fig. 8, B–F). Therefore, exosome secretion from SCs appears to be required to fully induce long-term postmating reprogramming of female behavior.

**BMP signaling regulates endolysosomal trafficking and is required for exosome secretion**

Blocking SC function and development affects multiple aspects of fecundity (Minami et al., 2012, Gligorov et al., 2013), but reduced BMP signaling and loss of exosome secretion in
Figure 6. SC exosomes interact with sperm in females. (A) Schematic of female reproductive tract in D showing mating plug (mp), uterus (ut), oviduct (ovi), and sperm storage organs (spermathecae [spt] and seminal receptacle [sr]) as well as the autofluorescent hindgut (HG). (B and C) w^{1118} female reproductive tract dissected 20 min after mating to either a control (B) or SC>CD63-GFP (C) male, imaged under identical confocal settings. Images show lumen of the female uterus (asterisks) containing sperm whose heads are visible with DAPI staining (arrowheads). (D and E) Female reproductive tracts 20 min after mating to a protamineB-RFP; SC>CD63-GFP male. (D) ProtamineB-RFP (prot-RFP), which marks sperm heads, accumulates in the anterior uterus (red arrowhead) and oviduct (red arrow). Most CD63-GFP–positive exosomes localize to the posterior uterus (green asterisk), but they can also be seen in the anterior uterus (green arrowhead) and oviduct (green arrow). The autofluorescent mating plug (closed asterisk) is shown. (E) CD63-GFP–positive exosomes colocalize with sperm heads marked by protamineB-RFP (open arrows). (F) Orthogonal view of a z stack through near-complete ring of CD63-GFP fused to ProtamineB-RFP sperm head (arrows). The confocal image below the blue line shows part of the female reproductive tract lumen. The two images above the blue line, separated by a white line, are green (top) and red/green (bottom) z stacks captured in the z plane marked in the bottom image. Note multiple pairs of parallel GFP-positive lines (arrowheads), potentially produced by sperm tail fusion. (G) These (arrowheads) and irregular extended lines of fluorescence (arrow) are also seen in G, which shows a maximum 3D projection image of a z stack from a female anterior uterus and oviduct where the epithelium is marked by actin>CD8-RFP (also shown in Video 3). (H) Female reproductive tracts were dissected and fixed at specific times after the start of mating to SC>CD63-GFP males. The frequency of exosome–sperm interaction events within the female reproductive tract was analyzed (n = 8 for each time point after the start of mating [ASM]). Only fusions to the sperm heads are included. Bars: (B and C) 50 µm; (D) 200 µm; (E and F) 5 µm; (G) 20 µm.
these cells specifically modulate female remating behavior. One possible explanation is that BMP signaling controls exosome production. Remarkably, antagonizing BMP signaling by expression of the negative regulator Dad almost completely blocked CD63-GFP–labeled exosome secretion (Fig. 5 A), strongly supporting this idea. Unfortunately, it was not possible to test the effect of elevated BMP signaling on exosome secretion by expression of a constitutively activated form of the BMP type I receptor Thickveins (Tkv\textsuperscript{ACT}, containing a Q199D substitution; Hoodless et al., 1996). The hypertrophic SCs induced by expression of this construct protrude into the AG lumen and shed large amounts of GFP-positive cellular debris (Leiblich et al., 2012), interfering with exosome counting.

We tested whether BMP signaling might modulate exosome secretion by altering endolysosomal trafficking in SCs, using live imaging of CD63-GFP–expressing cells. In contrast to the effect of \textit{ALiX} and \textit{Hrs} knockdown (Fig. 5, C and D), mMVBLs in \textit{Dad}-expressing SCs contained unusually high levels of internalized CD63-GFP (Fig. 5 D), indicating that BMP signaling is not required for ILV formation but must control a key trafficking and/or maturation event from the mMVBL to the plasma membrane and lysosomes, where GFP fluorescence would be lost. Indeed, SCs overexpressing Tkv\textsuperscript{ACT} had significantly fewer, but much larger, mMVBLs (P = 0.04; Fig. 5, G and I) with no intraluminal fluorescence, supporting this model. Numbers of iLEs were elevated (Fig. 5 H), and more of these cells than control cells (17/19 versus 16/31; P = 0.003, Fisher’s exact test) contained multiple SVs clustered around the enlarged mMVBL, consistent with the idea that there is increased bulk trafficking into the large acidic compartment. We therefore conclude that BMP signaling controls a key endolysosomal trafficking step in SCs required for exosome secretion, and this potentially explains the role of SC-specific BMP signaling in modulating female postmating behavior.

Because BMP signaling drives SC growth, as measured by relative size of SC versus neighboring MC nuclei (Leiblich et al., 2012), we tested whether exosome formation or secretion might be involved in this. Interestingly, although nuclei of SCs expressing either \textit{ALiX-RNAi} or \textit{Rab11DN} were reduced in size, nuclear size was increased in \textit{Hrs-RNAi}–expressing SCs (Fig. 9). This suggests that ESCRT-dependent ILV formation is not required for SC growth.
Reprogramming female behavior with male exosomes

Corrigan et al.

Western blot analysis of transferred seminal fluid and live imaging of giant MVBs in SCs to test our hypothesis that SCs produce exosomes. We primarily used the human CD63-GFP tetraspanin marker in our analysis. However, GFP-positive puncta were also observed in large secretory compartments of SCs expressing cytosolic GFP, and exosome-sized vesicles in MVBs and the AG lumen were observed in EM analysis of wild-type glands (Fig. S2), confirming their presence in nontransgenic flies. Because exosomes can be loaded with many cellular components, our findings provide a potential explanation for the observation that AGs of several insects, including Drosophila, secrete intracellular proteins (Walker et al., 2006; Sirot et al., 2011).

Figure 8. Knockdown of ALiX in SCs selectively affects female postmating receptivity to other males. (A) Proportion of premated 4-d-old males of different genotypes unable to prevent all females it subsequently mates with from remating (*, P < 0.05; **, P < 0.01, Fisher’s exact test). (B and C) Egg counts (B) and progeny counts (C) from mated females before remating experiments were performed (analyzed by unpaired two-tailed Student’s t test after a Shapiro–Wilk test to confirm normality). (D–F) Mating times (D, **, P < 0.01, Student’s test), proportion of males that mate within the first 40 min of exposure to females (E) or within 40 min of the end of previous mating (F), were also analyzed (using Fisher’s exact test for E and F). Values inside bars show the number of males tested (n). Error bars indicate ±SE. Data shown are from a single representative experiment out of two repeats. DN, dominant negative.

Discussion

Seminal fluid synthesized by male reproductive glands has a powerful influence on fertility, affecting multiple sperm activities and altering female behavior, in some cases directly conflicting with female reproductive interests. Several previous studies have revealed an important function for seminal peptides in Drosophila (Chen et al., 1988; Wolfner, 1997) and mammals (Park et al., 2011; Kershaw-Young et al., 2012) in these processes. However, in this study, we present the first in vivo evidence that exosomes also play a key role and identify a completely novel role for BMP signaling in regulating this process.

SCs secrete exosomes: A new in vivo model to study exosome biogenesis

Exosome biogenesis, secretion, and uptake have been previously studied in Drosophila (Gross et al., 2012; Koles et al., 2012; Beckett et al., 2013). However, the small size of exosomes, MVBs, and fly tissues makes these processes difficult to analyze in vivo. The AG contains only nanoliter volumes of secretions, making it impractical to use standard exosome analysis techniques, such as ultracentrifugation and Nanosight Tracking Analysis (Vlassov et al., 2012). Like other studies in flies, we used genetic and imaging approaches to test the identity of SC-specific CD63-positive puncta. In addition, we used Western blot analysis of transferred seminal fluid and live imaging of giant MVBs in SCs to test our hypothesis that SCs produce exosomes.

We primarily used the human CD63-GFP tetraspanin marker in our analysis. However, GFP-positive puncta were also observed in large secretory compartments of SCs expressing cytosolic GFP, and exosome-sized vesicles in MVBs and the AG lumen were observed in EM analysis of wild-type glands (Fig. S2), confirming their presence in nontransgenic flies. Because exosomes can be loaded with many cellular components, our findings provide a potential explanation for the observation that AGs of several insects, including Drosophila, secrete intracellular proteins (Walker et al., 2006; Sirot et al., 2011).

Other evidence strongly supports the idea that CD63-positive puncta secreted from SCs are exosomes and not vesicles shed from the plasma membrane. This includes the observation that CD63-positive puncta are found inside both acidic Rab7-positive MVB-like compartments as well as nonacidic Rab11-positive vacuoles and require the ESCRT and ESCRT-associated proteins Hrs and ALiX, as well as several Rab5 linked to mammalian exosome secretion, to be formed and secreted. Secreted puncta counts have been used previously in flies to study genetic control of exosome secretion (Gross et al., 2012). A criticism of this approach is that reduced puncta numbers may merely reflect aggregation. However, the transfer of CD63-GFP to females was drastically reduced in mutant backgrounds, arguing...
et al., 2012 versus Colombo et al., 2013), Hrs (Edgar et al., 2014), and Evi (Beckett et al., 2013). If different exosome subtypes are made in SCs, these cells should offer an ideal system to study their differential regulation.

The remarkably large size of endosomal compartments in SCs provides new opportunities to study exosome biogenesis in vivo. To date, many studies of the intracellular exosome against a simple aggregation model. Furthermore, because genetic manipulation of ESCRT function does not alter other secretory processes in SCs (Figs. 5 K and S4), this strongly implicates the endocytic pathway in secretion of tagged CD63.

Studies of exosomes in *Drosophila* as well as mammals already suggest that multiple exosome subtypes exist and may be regulated differently, e.g., different roles for ALiX (Baietti et al., 2012 versus Colombo et al., 2013), Hrs (Edgar et al., 2014), and Evi (Beckett et al., 2013). If different exosome subtypes are made in SCs, these cells should offer an ideal system to study their differential regulation.

The remarkably large size of endosomal compartments in SCs provides new opportunities to study exosome biogenesis in vivo. To date, many studies of the intracellular exosome...
biogenesis machinery and endolysosomal trafficking in higher eukaryotes have relied on expressing an activated form of Rab5 (Stenmark et al., 1994; Hirota et al., 2007; Wegner et al., 2010; Dores et al., 2012; Schroeder et al., 2012) or addition of the ionophore monensin (Savina et al., 2002) in cell culture to artificially enlarge the endolysosomal compartments, disrupting normal trafficking events. Hence, our new SC in vivo model should allow us to reinvestigate previously reported regulators of exosome biogenesis and identify functional differences in trafficking phenotypes, as we have seen for Hrs and ALIX.

Our study has already revealed a surprisingly dynamic interaction between the secretory and endolysosomal systems in SCs. Communication between these compartments using vesicular transport and tubulation processes has been reported in other cell types in flies and mammals (Savina et al., 2005; Minogue et al., 2006; Burgess et al., 2012), but our study suggests that direct fusion can also be involved. Indeed, our data are also consistent with mMVBLs forming after fusion between SVs and iLs (Fig. 2 D), suggesting that fusion events may play a critical role in establishing distinct compartments within SCs. In light of this dynamic flux between compartments, it remains unclear whether CD63-GFP–labeled exosomes might be released by the classical route involving mMVBL fusion to the plasma membrane or via an intermediate secretory compartment.

**SC exosomes have complex physiological functions**

Although most analysis of the fly AG has highlighted roles for MC products, such as SP (Chen et al., 1988; Chapman et al., 2003), in reprogramming female postmating responses, several recent studies have also suggested a central but poorly defined function for SCs (Leiblich et al., 2012; Minami et al., 2012; Gligorov et al., 2013). A transcriptional program regulated by the Hox gene Abd-B controls vacuole formation in SCs (Gligorov et al., 2013). Our findings now indicate that at least one of the effects mediated by SCs, altered receptivity to remating, requires exosome secretion.

It is difficult to accurately estimate the frequency of SC exosome–sperm fusion events in each female fly because they can probably only be visualized transiently, and many may involve fusion to the very long sperm tail. Sperm play an essential role as mediators of SP-dependent postmating effects in females (Liu and Kubli, 2003; Peng et al., 2005), so it is plausible that exosome fusion to sperm may modulate specific SP functions. Another appealing hypothesis is that SC exosomes also interact with the female reproductive tract to influence female behavior. However, whatever the target tissues, our data clearly demonstrate a role for SC exosomes in female reprogramming. Furthermore, like human prostasomes (Arenti et al., 1997; Park et al., 2011), SC exosomes fuse with sperm, highlighting possible conserved roles for exosomes in male reproductive biology. In prostate cancer, prostasomes are inappropriately secreted into the bloodstream (Sahlén et al., 2004; Tavosiddana et al., 2011), so that other cells in the body may be subjected to these powerful reprogramming functions, potentially supporting tumor–stroma interactions and metastasis (Ronquist et al., 2010; Ge et al., 2012).

**BMP-dependent regulation of endolysosomal trafficking and exosome secretion**

Reducing BMP signaling in SCs inhibits exosome secretion and leads to the formation of a novel mMVBL compartment that is filled with fluorescent CD63-GFP. A simple interpretation of this result is that MVBL compartments in these cells do not mature properly, blocking exosome secretion. Consistent with this, increasing BMP signaling in these cells produces a highly enlarged acidic compartment.

Previous studies have shown that blocking endosomal maturation by knockdown of the early ESCRT component Hrs increases the size of immature endosomal class E compartments lacking ILVs and also results in increased BMP signaling (Piper et al., 1995; Jékely and Rørth, 2003; Chanut-Delalande et al., 2010). Our data demonstrate that elevated BMP signaling increases mMVBL size, suggesting that there is a complex bidirectional interaction between mMVBL maturation and size and the level of BMP signaling in SCs.

Our findings are consistent with a model in which BMP signaling also controls SC growth by driving endolysosomal trafficking and maturation events. Late endosomes and lysosomes have previously been shown to house major nutrient sensors and cell growth machinery, including the mTORC1 complex (Goberdhan, 2010; Ögmundsdóttir et al., 2012), which is activated by intraluminal amino acids. Interestingly, the growth rate of knockdown cells with reduced ESCRT function appears to correlate with mMVBL size (Fig. 5 I) rather than exosome secretion rate. We now need to test whether growth in these cells is mTORC1 dependent.

Whatever the explanation for the growth defects in SCs, our data very clearly implicate BMP signaling in the regulation of endolysosomal trafficking and exosome secretion. It will now be important to test whether BMP signaling plays a similar role in mammalian glands that secrete exosomes, such as prostate and breast, and determine whether this role is affected in diseases such as cancer.

**Materials and methods**

**Fly stocks**

The following stocks were used: esgl/CyO (esgl-GAL4 tub-GAL80° UAS-FLP/P CyO); UAS-GFP°, actin>FRT>CD2>FRT>GAL4/TM6 (Jiang et al., 2009); a gift from B. Edgar, Center for Molecular Biology, University of Heidelberg, Germany; esgl-GAL4 (Zhang et al., 2007; see FlyBase), tub-GAL80°, P(UAS-FP1.D) P(UAS-GFP.nls), and actin>FRT>CD2>FRT>GAL4/TM6 are described in FlyBase, UAS–CD63-GFP (Panáková et al., 2005); a C-terminal fusion of full-length human CD63 with eGFP-C1, which was then inserted into the pUAST vector [Brand and Perrimon, 1993]; see FlyBase, a gift from S. Eaton, Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany), tub-rab11-YFP, tub-rab7-YFP and tub-rab5-YFP (gifts from J.-P. Vincent, Medical Research Council National Institute for Medical Research, London, England, UK), Acp26Aa-GAL4 (Chapman et al., 2003; ~1.4 kb fragment upstream of the Acp26Aa coding region fused to GAL4); a gift from M. Wolfrun, Cornell University, Ithaca, NY), dix-GAL4 (Rideout et al., 2010); a GAL4 gene trap inserted into the first coding exon of the dix gene; a gift from S. Goodwin, University of Oxford, England, UK), spi-GAL4 (Hayashi et al., 2002; spig206; see FlyBase), UAS–ALIX RNAi (RNAi1, <v32047 [Vienna Drosophila Resource Center]; RNAi2, HMS00298 [Bloomington Drosophila Stock Center] containing nonoverlapping target sequences; Dietzl et al., 2007; Ni et al., 2008), UAS–Hrs RNAi (RNAi1, HMS00841 [Bloomington Drosophila Stock Center]; RNAi2, HMS00842 [Bloomington Drosophila Stock Center]; Ni et al., 2008), UASp-YFP.Rab11.S25N (Zhang et al., 2007; see FlyBase).
Mating experiments to analyze exosome transfer (Escola et al., 1998). We have not confirmed that it is transcribed in SCs because an in
strongly argues that shedding of membrane debris does not take place in
after multiple matings without affecting expression in the gland (Fig. 5)
dramatically reduces the levels of CD63-GFP in the AG lumen in young males
comparison. The observation that blocking ESCRT-dependent events in SCs
in living SCs, subcellular structures and intracompartment puncta are much
better preserved than in fixed tissue (compare Fig. 1, E and G), so wherever
possible, live staining was used for classifying and counting
compartments. We expressed several UAS-regulated tagged markers for
endolysosomal compartments in SCs, e.g., HRP-Lamp (Juhász et al., 2008)
and spin-GFP (Sweeney and Davis, 2002), but they all altered the ratios of
acidic and nonacidic compartments in these cells, so we could not use
them as an additional tool to confirm our conclusion that large acidic
compartments in SCs are late endosomes or lysosomes. CD63-GFP puncta
that could be seen in the large acidic compartments of SCs were strongly
fluorescent. This is consistent with observations in mammalian cells, in which
CD63 is typically concentrated into IVVs within acidic MVBs before secrec
tion (Escola et al., 1998).

Pulse–chase experiments
A short (8 h) pulse of CD63-GFP expression was induced by inhibiting the
temperature-sensitive GAL4 transcriptional repressor GAL80ts at 28.5°C.
This was followed by a chase period at 18°C of 0–60 h. Note that the
CD63-GFP transcript is likely to persist once the pulse has ended, and so,
new fusion protein expression will continue during the chase period.

Analysis of exosome secretion and regulation
Because the AG lumen contains only nanoliter volumes of secreted fluid of
complex composition (Fig. S2 G), including the exosomes made from just
4 SCs, it was not practical to use standard isolation approaches (Vlassov et al.,
2012) to study SC exosomes. In vivo exosome quantification and analysis of ANCE
staining in the AG lumen (Figs. 5 and S4, respectively), newly eclosed males were incubated at 28.5°C to induce transgene expression. After 2 d,
each male was mated to three white-eyed females (esgf/O; >ALIXRNAi1, esgf/O; >Rab11DN, or esgf/O) were shifted to 28.5°C to
induce transgene expression. Individual males were then added after 3 d
to five 2–10-d-old virgin w1118 females (for a specific group of control and
 Females were of identical age) overnight at 28.5°C. The next
morning, these females were then replaced with three 2–5-d-old virgin
w1118 females for 3 h and watched to score timing of mating events,
after which the females were separated and incubated at 25°C. For
crosses in which at least two females had mated, these females were transferred
to separate, fresh vials on each of the next 3 d. Egg counts and progeny
counts were recorded for each vial. Each female was then introduced to a
dominantly marked (CyO; R0) white-eyed male and left for 3 h. Mating
events were confirmed by the presence of CyO; R0 progeny. The absence of
effects on egg laying and fertility in males in which exosome secretion is
inhibited supports the conclusion that the secretion of most seminal proteins
is unaffected by this treatment.

LysoTracker staining
Glands were dissected in ice-cold PBS and left in ice-cold 5 µM LysoTracker
red DND-99 (Invitrogen) in PBS for 5 min. They were then washed in ice-
cold PBS for 5 min and mounted in PBS using a coverslip bridge for imag
ing. These specimens were imaged within 1 h but showed no signs of cell
death or deterioration over several hours.

Preparation of AGs for antibody staining
The age of dissected flies is given as days after eclosion at 28.5°C. Immunoo
staining of the AG was performed as previously reported (Leiblich et al.,
2012). Dissections in cryoprobe were performed in 4% paraformaldehyde in PBS
with a minimum total fixation period of 15 min followed by a 20-min wash in
PBST-O.3% and then a 30-min wash in PBST-male (PBST-O.3% and 10%
goose serum). All washes were performed at room temperature (22°C).
not represent a reduced number of more intensely fluorescent structures. Rab11DN is not secreted into the AG lumen (Fig. S5, B versus A), so the limited number of fluorescent puncta in the lumen in this genetic background represents CD63-GFP-positive structures. The values represent the mean particles in a 7,225-μm² luminal area, averaged over a minimum of nine glands and calculated as a percentage of the control value from a parallel experiment.

For nuclear size data, 10 glands for each genotype were analyzed. For each gland, the areas of nuclei for three different SCs, and for each SC, nuclear areas for three surrounding MCs, were measured using ImageJ by outlining nuclei and measuring the enclosed area. For each SC, the mean nuclear size of neighboring MCs was calculated, and relative nuclear size values were obtained by dividing each SC value by the corresponding MC value. These ratios were averaged across 10 glands to give the mean clear size ratio. Individual experimental genotypes were always analyzed in parallel with a control that did not express the transgene.

EM
3-dold w1118 male reproductive tracts were dissected out and stored overnight in fixative containing 2.5% glutaraldehyde and 4% formaldehyde in PBS, pH 7.2, washed with PBS, postfixed with 1% osmium tetroxide, dehydrated, and embedded in Spurr’s epoxy resin between two sheets of polythene. Ultrathin sections were prepared with an ultratome (Ultracut S; Reichert), mounted on formvar-coated slot grids, stained with 2% uranyl acetate and lead citrate, and observed with an electron microscope (1010; JEOL) operated at 80 kV. Although several methodologies for fixation were tested, membranes in AG preparations were often poorly preserved.

Statistical analysis
All compartment and exosome counts, as well as nuclear and mMVLB size measurements, involved analysis of SCs from multiple independent animals and were repeated in at least three separate experiments. Data were analyzed using Excel (Microsoft) or SPSS (IBM). Normality of the data was assessed using a Shapiro–Wilk test. Based on this test, data were analyzed using a two-tailed unpaired Student’s t test or Mann–Whitney U test for single-pair comparisons. Remating data and mating times (Fig. 8) were analyzed using Fisher’s exact test. Remating results shown are from a single representative experiment including pooled data collected from crosses set up over several days. These experiments were repeated twice.

Online supplemental material
Figure S1 shows SC-specific secretion of CD63-GFP exosomes and characterization of SC vascular compartments. Figure S2 shows colocalization of GFP with the anti-CD63 antibody signal, except in specific mMVBs. Figure S3 shows individual channels from a pulse-chase analysis in Fig. 3 (A–F). Figure S4 shows the effects of knocking down membrane trafficking regulators on ANCE secretion. Figure S5 shows transfer of SC-specific CD63-GFP to neighboring MCs and the absence of Rab11-YFP on exosomes. Video 1 depicts a live-imaging sequence showing an acidic mMVB fusing to a nonacidic SC in SCs (Fig. 4 A). Video 2 depicts a live-imaging sequence showing an invagination of a CD63-GFP-positive membrane from the mMVB limiting membrane (Fig. 4 B). Video 3 shows a rotating 3D projection of the image shown in Fig. 6 G. Video 4 shows a rotating 3D projection of the image in Fig. 7 C. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.201401072/DC1. Additional data are available in the JCB DataViewer at http://dx.doi.org/10.1083/jcb.201401072.dv.
