Sites of Inhibition of Mitochondrial Electron Transport in Macrophage-injured Neoplastic Cells

DONALD L. GRANGER and ALBERT L. LEHNINGER
Department of Physiological Chemistry, Johns Hopkins University, School of Medicine, Baltimore, Maryland 21205

Abstract

Previous work has shown that injury of neoplastic cells by cytotoxic macrophages (CM) in cell culture is accompanied by inhibition of mitochondrial respiration. We have investigated the nature of this inhibition by studying mitochondrial respiration in CM-injured leukemia L1210 cells permeabilized with digitonin. CM-induced injury affects the mitochondrial respiratory chain proper. Complex I (NADH-coenzyme Q reductase) and complex II (succinate-coenzyme Q reductase) are markedly inhibited. In addition a minor inhibition of cytochrome oxidase was found. Electron transport from α-glycerophosphate through the respiratory chain to oxygen is unaffected and permeabilized CM-injured L1210 cells oxidizing this substrate exhibit acceptor control. However, glycerophosphate shuttle activity was found not to occur within CM-injured or uninjured L1210 cells in culture hence, α-glycerophosphate is apparently unavailable for mitochondrial oxidation in the intact cell. It is concluded that the failure of respiration of intact neoplastic cells injured by CM is caused by the nearly complete inhibition of complexes I and II of the mitochondrial electron transport chain. The time courses of CM-induced electron transport inhibition and arrest of L1210 cell division are examined and the possible relationship between these phenomena is discussed.

Macrophages activated by lymphocyte-derived mediators and by bacterial components such as lipopolysaccharide are cytotoxic for neoplastic cells in vitro (see reference 1 for review). Binding of the macrophage to the target cell is required for cytotoxicity (2), but phagocytosis does not necessarily occur. Cytotoxic macrophages (CM) inhibit target cell DNA synthesis within 4–6 h after initial contact (3, 4). In the case of some neoplastic cell lines death occurs in hours or days following CM-induced cytostasis (5, 6), but other cell lines exhibit remarkable resistance to cytolysis (7).

Recently it was found that neoplastic cells in contact with CM lose their capacity for mitochondrial respiration (8). This is not a secondary effect of target cell death because it occurred in cell lines that resist cytosis under conditions of the in vitro assay. For example, a line of lymphoblastic leukemia cells (L1210) injured by CM remain viable and amitotic for several days in culture (8). During this time they derive adenosine triphosphate (ATP) from glycolytic conversion of glucose to lactate at a very high rate (8). CM-injured L1210 cells eventually recover their capacity for cell division and this event correlates with resumption of mitochondrial respiration (9).

At the outset of this study it was known that CM-injured L1210 cells did not respire when suspended in either buffered saline (endogenous respiration) or in complete culture medium containing precursors of substrates for mitochondrial oxidation (8). The lack of respiration under these conditions could be explained by an extramitochondrial defect, for example, inhibition of plasma membrane transport for a necessary substrate, or by a mitochondrial effect, either enzyme inhibition or loss of a critical substrate, cofactor, or ion. An obvious approach to resolving these two possibilities would involve isolating mitochondria from CM-injured L1210 cells and examining respiratory chain redox reactions in the presence of added substrates, cofactors, etc. This avenue proved technically difficult because of the limited number of L1210 cells that could be injured by contact with CM in cell culture. Instead, we applied a method for measuring mitochondrial functions in whole cells permeabilized with digitonin (10–12). Because the molar ratio of cholesterol to phospholipid in eukaryotic plasma membranes is significantly greater than in mitochondrial membranes, binding of membrane cholesterol by digitonin leads to a selective increase in permeability of the plasma membrane (13, 14). Under defined conditions the acceptor control ratio (ACR) of digitonin-permeabilized hepatocytes and Ehrlich ascites cells was equal to or greater than that obtained with mitochondria isolated from the same cells using standard methods (15). An
added advantage of this method for comparing CM-injured L1210 cells with uninjured cells was that measurements could be expressed on a per cell basis. This obviated errors inherent in the isolation process due to loss of mitochondria as well as inclusion of nonmitochondrial protein in the two types of samples.

In the experiments that follow several mitochondrial functions were measured in digitonin-permeabilized L1210 cells before and after injury by CM. The results show that CM-injured L1210 cells exhibit blocks in the respiratory chain at least two loci. The CM-induced inhibition is selective since other mitochondrial functions remain intact.

**MATERIALS AND METHODS**

**Reagents**

Rotenone (K and K Laboratories, Plainview, NY), antimycin A, and oligomycin (Sigma Chemical Co., St. Louis, MO), and carbonyl cyanide p-trifluoromethoxyphenylhydrazone (FCCP) (Dupont Co., Wilmington, DE) were dissolved in absolute ethyl alcohol. Digitonin (Grand Island Biological Co., Grand Island, NY) was prepared according to Kun et al., (16), and dissolved in dimethyl sulfoxide. The small amounts of these solvents alone added to cell suspensions had no effect on any of the measurements made. Potassium tetramethylphenylenediamine (TMPD) (Sigma Chemical Co.) and KCN were prepared fresh and neutralized just before use. Ferricytochrome c (Sigma Chemical Co.) stock solution was stored frozen and the concentration was determined spectrophotometrically after reduction with dithionite (ε = 27.6 mM⁻¹ at 550 nm).

**Murine Cytotoxic Macrophages**

Outbred Swiss female mice 2-mo old (Microbiological Associates, Walkersville, MD) served as the source of macrophages. Mice were immunized intraperitoneally with 10 colony forming units of Mycobacterium bovis, strain BCG, Pasteur (TMC No. 1011, Trudeau Institute, Inc., Saranac Lake, NY). 2 wk later an intraperitoneal shot of 1 ml 10% proteose peptone (Difco Laboratories, Detroit, MI) was given. 3 d later peritoneal exudate cells were harvested and plated in petri dishes (Costar, Cambridge, MA) at 1.5 × 10⁶ cells per cm² surface area for in vitro culture. The method used for preparing adherent monolayers of murine CM has been described in detail (8). CM were cultured at 37°C under 5% humidified air, 9% CO₂ atmosphere in Dulbecco's Modified Eagles Medium (Grand Island Biological Co.) supplemented with 10% horse serum (Sterile Systems, Inc., Logan, UT), additional glucose (15.5 mM final concentration), HEPES, 20 mM, pH 7.4, Penicillin G, 100 U/ml, and streptomycin, 100 μg/ml (referred to as: culture medium). Endotoxin (ET) (phenol extract of Escherichia coli 0128:B12 from Sigma Chemical Co.), 10 ng/ml, was added to culture medium as the final stimulus to activate macrophages to the cytotoxic state (17). At this concentration ET had no effect on the doubling time or on mitochondrial respiration of the neoplastic target cells used in these experiments.

**CM-injured Neoplastic Cells**

A murine lymphoblastic leukemia cell line (L1210) was used as target for CM. L1210 cells were maintained in culture medium in suspension and passed twice weekly. For coculture with CM, log phase L1210 cells were washed by centrifugation and added to freshly explanted CM at a final cell density of 2.5 × 10⁶ per cm² culture dish surface area. Culture medium volume was 0.5 ml/cm². After a suitable incubation period L1210 cells were rinsed from CM monolayers as previously described (8). Experiments with radiolabeled cells showed that essentially all L1210 cells are removed from CM using this procedure. L1210 cells cocultured with CM are termed injured cells. Control or uninjured L1210 cells were incubated in culture medium + ET without CM for the same length of time.

**Cell Counts**

Both measurements of cell growth and oxygen consumption rates were based on the number of viable L1210 cells per ml. Cells were counted electronically (Model ZBI, Coulter Electronics Inc., Hialeah, FL) and viability was assessed microscopically by trypan blue (0.04% wt/vol) exclusion. L1210 cells rinsed from CM monolayers were invariably contaminated with some macrophages that dislodged from the plastic surface during rinsing. Cell volume distribution curves of L1210 cells alone and macrophages alone, rinsed from CM monolayers, were generated using the Coulter counter. The two cell populations showed very little overlap based on the larger volume of L1210 cells compared to CM. Thus, by adjusting the cell counter lower threshold to a setting corresponding to the nadir between the two populations, most contaminating CM were excluded from the electronic cell counts. Cell counts using appropriate controls revealed that L1210 cell suspensions rinsed from CM monolayers could be enumerated with <2% error due to contaminating macrophages and consequently no corrections were made.

**Respiration Measurements**

L1210 cells rinsed from CM were washed twice by centrifugation (4°C, 500 g) with 0.25 M sucrose containing 20 mM HEPES (pH 7.1), and 10 mM MgCl₂. The pellet of packed cells was then resuspended in a small volume of the same medium and stored on ice. Oxygen consumption was measured with a Clark electrode in a water jacketed chamber (Gibson Medical Electronics, Inc., Middle- dle, WO) stirred with a magnetic stirrer. The electrode signal was fed through suitable amplification into a strip chart recorder (Sargent Welch Model DSRG-2, Sargent-Welch Co., Skokie, IL) that was calibrated over a 0-100% scale. The temperature was 37°C in a medium consisting of air-saturated 0.25 M sucrose, 20 mM HEPES, pH 7.1, 2 mM KCl, 10 mM MgCl₂, and 1.0 mM ADP (respiration medium). The oxygen consumption under these conditions was taken to be 390 ng atoms/ml·50-100 μl of concentrated cell suspension were added to 1.2 ml respiration medium and then three small aliquots were removed from the electrode chamber for cell counts. The chamber was sealed with a stopper containing a capillary port for additions. Oxygen consumption rates are expressed in nanogram atoms per minute per million L1210 cells based on the mean of three separate cell counts for each trace.

Control experiments were performed to determine whether contaminating macrophages dislodged from CM monolayers during removal of L1210 cells contributed to oxygen consumption measurements. Their contribution was found to be negligible.

**Mitochondrial Oxidation of NADH**

Uninjured or CM-injured L1210 cells were washed by centrifugation in cold 0.25 M sucrose containing 20 mM HEPES, pH 7.1, and 10 mM MgCl₂, and resuspended in 10 ml of this medium. A cell count was made and a small aliquot of 10% digitonin (5 μl/10⁶ cells) was added while mixing. Then 40 μl of sucrose medium was added and the cells were pelleted (4°C, 800 g) and resuspended in 0.5-1.0 ml sucrose medium to give ~5 × 10⁶ cells/ml. Counts were made on this stock suspension of permeabilized cells. This procedure resulted in >99% trypan blue emitting L1210 cells that retained their spherical morphology. Permeabilization followed by centrifugation effectively eliminated endogenous respiratory substrates. These cells did not consume oxygen without added substrate but addition of malate or succinate, but not NADH, initiated respiration. Ferricytochrome c, 25 μM final concentration, was added and the permeabilized cells were sonicated (Model W185, Branson Sonic Power Co., Danbury, CT) with three 6-s bursts at an output of 50 W. Known aliquots of the sonicated cell suspension were added to equilibrated respiration medium for oxygen consumption measurements. Counts of the stock cell suspension before sonication were used to calculate the rates. Permeabilized cell sonicates prepared by this method using both uninjured and CM-injured L1210 cells oxidized α-glycerophosphate at equal rates (~4 ng atoms oxygen per minute per 10⁵ cells).

**RESULTS**

**Mitochondrial Respiration in L1210 Cells Permeabilized with Digitonin**

Before comparing mitochondrial functions of CM-injured and uninjured L1210 cells, it was necessary to establish conditions for selective permeabilization of the plasma membrane with digitonin. Increasing concentrations of digitonin were added to L1210 cells in the presence of succinate, rotenone, ADP, and P₄ (state 3 conditions), and the rate of O₂ consumption was measured (Fig. 1). Without digitonin the rate is very low, due primarily to low permeability of the plasma membrane to succinate. Maximal state 3 respiratory rate was obtained with as little as 0.0025% digitonin. Significant inhibition of the state 3 rate does not take place on further increases in digitonin, up to 0.025%. Identical titration curves were obtained with malate and α-glycerophosphate as substrates, suggesting that the site of digitonin-induced inhibition at high concentrations...
is not at the level of the individual dehydrogenases, which catalyze the oxidation of these substrates.

Digitonin at concentrations up to 0.02% did not increase the state 4 respiratory rate (Fig. 1A). At higher digitonin concentrations some inhibition was produced, parallel to the effect observed in state 3. The acceptor control ratio (state 3 rate/state 4 rate) at 0.005% digitonin in such experiments was ~3.7, comparable to that observed in mitochondria isolated from L1210 cells using standard methods (18). Use of digitonin to permeabilize the plasma membrane thus has an ample safety margin before mitochondrial functions are affected.

L1210 cell density was then varied, with digitonin concentration held constant at 0.005%, and the rates of O2 consumption in state 3 were measured. A linear relationship was observed within the range of cell densities tested (Fig. 1B). Based on the results shown in Fig. 1A and B the standard permeabilization procedure adopted for the experiments that follow employed 0.005% digitonin with an approximate cell density of 5 x 10^6/ml.

It was also important to determine whether CM-injured and uninjured L1210 cells were permeabilized by similar concentrations of digitonin. This was examined by measuring entry of trypan blue (molecular weight = 961) at increasing digitonin concentrations. The dose-titration curves for L1210 cells before and after injury by CM were essentially identical (Fig. 1C). In this experiment lower concentrations of digitonin sufficed presumably because L1210 cell densities were more than 10 times less than those used for O2 uptake measurements as in Fig. 1A. Thus CM-induced injury did not appear to alter the properties of the plasma membrane of L1210 cells that render the cells susceptible to permeabilization by digitonin.

Addition of Mitochondrial Substrates and Cofactors to CM-injured L1210 Cells

At the top of Fig. 2 a simplified scheme of the mitochondrial respiratory chain is presented for reference. The oxygen electrode trace B in Fig. 2 shows that when uninjured L1210 cells are permeabilized with digitonin in the presence of malate, ADP, and P_i (state 3 conditions) rapid linear O2 consumption occurs. Malate enters the mitochondrial matrix via the electro-neutral dicarboxylate carrier (19) and, in L1210 cells, is largely oxidized by malic enzyme to yield NADH, pyruvate, and CO2 (20). The NADH formed is in turn oxidized by the respiratory chain. Rotenone, which inhibits complex I (NADH-coenzyme Q reductase), halts oxygen consumption. The rate of respiration by an equal number of CM-injured L1210 cells under the same conditions is markedly reduced (Fig. 2, trace A). Addition of succinate, which bypasses the rotenone block, leads to resumption of respiration in uninjured L1210 cells, but again, in CM-injured cells there was only a slight response (Fig. 2 traces B vs. A). Succinate respiration was stopped entirely by addition of antimycin A; oxygen consumption resumed when tetramethylphenylenediamine (TMPD) was added to donate electrons to cytochrome c. The rate of oxidation of TMPD by CM-injured L1210 cells was slightly reduced when compared to uninjured L1210 cells. A series of experiments was performed to check the consistency of the results shown in Fig. 2. These data are listed in Table I. They show that extensive inhibition of NAD-linked and succinate respiration is a constant finding when L1210 cells are cocultured with CM for 20 h. Other NAD-linked substrates (pyruvate, citrate, isocitrate, glutamate, and 3-ketoglutarate), added alone or in combination with malate, were not oxidized by CM-injured L1210 cells (data not shown). NADH, which would not be expected to enter the mitochondrial matrix when added to permeabilized L1210 cells, likewise had no effect on CM-injured cells (data not shown). Under these conditions added malate and endogenous mitochondrial substrates are responsible for NAD-linked respiration of uninjured cells. In the absence of added malate the O2 uptake rate slows as endogenous substrates are depleted. A linear rate of respiration is restored on addition of excess malate. If uninjured L1210 cells are first permeabilized and then repeatedly washed in sucrose medium by centrifugation, endogenous respiration is reduced to zero. Under these conditions NAD-linked respiration is totally dependent on added substrate. Parallel treatment of CM-injured L1210 cells failed to restore NAD-linked respiration. Therefore, the inhibition of electron transport induced by CM cannot be "washed away" from the cells.

Under the conditions used for the experiments in Fig. 2 and Table I, inhibition of malate and succinate oxidation could be
due to either a block in translocation of ADP and/or Pi or inhibition of the F$_1$-ATPase complex. The data in Fig. 3 show that neither of these possibilities is the case. When the protonophore p-trifluoromethoxyphenylhydrazone (FCCP) is added to injured L1210 cells in the presence of malate, there is only an insignificant increase in O$_2$ consumption (trace A). As a control the effect of FCCP on NAD-linked respiration by uninjured L1210 cells in the presence of oligomycin is shown (trace B).

Also shown in Table I are the state 3 rates for another mitochondrial substrate, α-glycerophosphate. Electrons from α-glycerophosphate bypass the rotenone block as shown at the top of Fig. 2. Unlike the inhibited malate and succinate respiration, α-glycerophosphate is oxidized by CM-injured cells at the same state 3 rate observed with uninjured cells. This is an important finding because it shows that the respiratory chain between coenzyme Q and O$_2$ is functional in L1210 cells following CM-induced injury. It is evident that CM-induced injury leads to selective defects in the mitochondria of L1210 cells. Oxidation of the major mitochondrial substrates gener-
Concentrations used were those required to produce maximal respiration rates (substrates) or maximal inhibition under the conditions described in Materials and Methods. Values are mean ± SEM for at least five separate experiments.

L1210 cells had been incubated with or without cytotoxic macrophages for ~20 h. State 3 rates were initiated by adding digitonin, 0.005%, to L1210 cells in respiration medium containing substrates and inhibitors. State 3 rates for oxidation of NAD-linked substrates are rate-limiting step(s) for oxidation of NAD-linked substrates or formation of ATP from ADP in the state 3 rates for oxidation of NAD-linked substrates. The rate-limiting step(s) for oxidation of NAD-linked substrates or formation of ATP from ADP in the state 3 rates for oxidation of NAD-linked substrates must therefore be located before the point of coenzyme Q reduction.

Correlation between CM-induced Cytostasis and Inhibition of Mitochondrial Respiration

The time course of inhibition of malate and succinate oxidation was measured and these results are plotted together with the induction of cytostasis in L1210 cells injured by CM (Fig. 4A). This delayed onset has been observed by others measuring inhibition of DNA synthesis (3, 4). Inhibition of NAD-linked respiration begins between 2 and 4 h whereafter a steady decline in the state 3 rate occurs over the ensuing 10 h. Thus mitochondrial inhibition progresses slowly over a period of hours. This is in contrast to DNA synthesis, which attains maximal inhibition within 2 h of onset (4). With succinate as substrate, again, a progressive inhibition is seen but at a lower rate compared to NAD-linked respiration (Fig. 4C). Also plotted in Fig. 4C are the state 4 rates of CM-injured and uninjured cells in the presence of succinate and oligomycin. These rates are equal and constant for both uninjured and injured cells at each time point measured. During the period in which state 3 NAD-linked and succinate respiration is undergoing progressive inhibition the state 4 rate does not increase, suggesting that respiration remains coupled to phosphorylation.

In Fig. 5 the time course of inhibition of cell division and respiration is plotted over a 3-d period. In this experiment L1210 cells were incubated with CM for 23 h and then removed and cultured in fresh medium for an additional 47 h (Fig. 5A). Like the cytostatic effect, inhibition of both NAD-linked and succinate-linked respiration is not reversed by separating target cells from CM (Fig. 5). Oxygen consumption on α-glycerophosphate, which is unaffected at 20 h, remains at control levels on days 2 and 3 as well. This is the case for L1210 cells separated from CM on day 1 (Fig. 5D) or for L1210 cells cocultured with CM during the entire 3-d incubation (not shown).

At 70 h uninjured L1210 cells have reached the plateau phase of their growth curve (Fig. 5A). This has no effect on the rate of state 3 respiration in the presence of any of the substrates tested. Thus cessation of L1210 cell division in itself is not sufficient to explain the effects produced by CM on the respiratory chain of these neoplastic cells.

Activities of Selected Components of Mitochondrial Electron Transport

One or more of three possibilities could account for the inhibited respiration in CM-injured L1210 cells. First is inhibition of the dicarboxylate transport system of the inner mitochondrial membrane. Second, it is possible that either the

**FIGURE 3** Effect of uncoupler (FCCP) on CM-injured L1210 cells. Trace A: L1210 cells had been cocultured with CM for 21 h. Respiration medium contained 5.0 mM malate. L1210 cells were permeabilized with 0.005% digitonin. FCCP concentration was 80 nM. Numbers are rates of oxygen consumption (nanogram atoms per minute per 10^6 L1210 cells). Trace B: Uninjured L1210 cells. Conditions the same as in trace A except that respiration medium contained in addition, oligomycin, 100 nM.
matrix dehydrogenases are inhibited or their cofactors are missing or unreactive. The third possibility would be inhibition of both complex I (NAD-coenzyme Q reductase) and complex II (succinate-coenzyme Q reductase) of the electron transport chain. The third possibility was tested first.

Oxidation of NADH by complex I is difficult to measure in digitonin-treated cells because the inner mitochondrial membrane is impermeable to the pyridine nucleotides and because there are numerous other enzymes in the cells for which NADH is a reductant. These difficulties were circumvented by first disrupting the cells, including the inner mitochondrial membrane, by sonication and then assessing NADH oxidation by two criteria: the NADH oxidation must be linked to oxygen consumption and it must be inhibited by rotenone. Although the sonicated preparations of uninjured L1210 cells gave relatively low rates of NADH oxidation, the method was useful for comparison with CM-injured L1210 cells (Table II). In each experiment rotenone-sensitive NADH oxidation was markedly inhibited in L1210 cells injured by CM. The degree of inhibition (mean = 89%) was similar to that observed with NAD-linked substrate (i.e., malate, 92%, Table I). Rotenone-insensitive NADH oxidase activity was not affected in L1210 cells injured by CM (Table II).

The activity of succinate dehydrogenase (SDH) in complex II was measured using the artificial electron acceptor dye, phenazine methosulfate (PMS). Reduced PMS formed upon reaction with SDH is rapidly autoxidized and this reaction can be followed with an oxygen electrode (21). Although this assay may not detect the full activity of SDH (22), it was found to be
suitable for the purpose of comparing CM-injured L1210 cells with uninjured cells (Table III). When coenzyme Q is acceptor, electrons pass from reduced SDH through the respiratory chain to cytochrome oxidase. With PMS as electron acceptor the respiratory chain is blocked with antimycin A and cyanide. In both cases CM-induced injury results in significant loss of activity. Not presented in Table III are control experiments in which a known inhibitor of SDH, malonate, was found to inhibit succinate oxidation in injured L1210 cells using either assay method.

A small but consistent inhibition of the terminal segment of the respiratory chain from cytochrome c to oxygen was noted (TMPD plus ascorbate as substrate, Table I). Assay of cytochrome oxidase (23) was performed and the activity was calculated on a per cell basis. A consistent but relatively weak inhibition of cytochrome oxidase (range = 15–20%) was found when CM-injured L1210 cells were compared to uninjured cells. The activity of cytochrome oxidase in injured L1210 cells was 35 ng atoms oxygen per minute per 10⁶ cells (mean of seven experiments).

**Oxidative Phosphorylation in CM-injured L1210 Cells Respiring on α-Glycerophosphate**

The finding that CM-injured L1210 cells can oxidize α-glycerophosphate at the control state 3 rate raised two important questions: can mitochondrial ADP phosphorylation occur in the presence of this substrate and if so, is it available to intact L1210 cells under the conditions of in vitro culture? Measurement of the P:O ratio during oxidation of α-glycerophosphate would provide quantitative data on the efficiency of energy coupling. However, a disadvantage of the permeabilized cell method used here precluded direct ATP measurements. Multiple ATPase activities remain active in digitonin-permeabilized cells. Hence the efficiency of mitochondrial ATP synthesis cannot be accurately measured due to concomitant hydrolysis at extra-mitochondrial sites. Instead the ACR of CM-injured and uninjured L1210 cells oxidizing α-glycerophosphate were determined. This provides indirect evidence for coupling of electron transport to ATP synthesis. In a coupled system under state 3 conditions inhibition of the mitochondrial ATPase by oligomycin leads to an increased protonmotive force which depresses the rate of electron transport (24). An experiment of this type is shown in Fig. 6. Here the state 3 and 4 rates of CM-injured and uninjured L1210 cells were similar. However, when this experiment was repeated several times, a small but significant difference emerged (Table IV). The state 4 rate of CM-injured cells was significantly elevated and consequently the ACR of these cells was significantly decreased. State 3 rates of injured versus uninjured L1210 cells were not significantly different. The presence of acceptor control in CM-injured L1210 cells oxidizing α-glycerophosphate is strong evidence that electron transport is coupled to phosphorylation of ADP; however, the relative efficiencies cannot be quantified. The increased state 4 rates of injured L1210 cells suggest that coupling efficiency may be reduced, although direct measurement of ATP synthesis would be required to substantiate

* L1210 cells were incubated in the presence or absence of CM for ~20 h before respiration measurements.

* Addition of digitonin, 0.005%, to L1210 cells in respiration medium containing α-glycerophosphate 10 mM, and rotenone 100 nM (state 3). State 4 rate is same conditions as state 3 but with addition of oligomycin 100 nM.  
* Determined by Student's t test.

* Values are means ± SEM for seven separate experiments.
certain neoplastic cells (26). The occurrence of the α-glycerophosphate dehydrogenase. However, we found no evidence for glycerophosphate shuttle activity either in uninjured or injured L1210 cells, despite the fact that the mitochondrial dehydrogenase is functional and unaffected by macrophage cytotoxicity. A host of macrophage-derived cytotoxins have been identified (28–33). It is not clear from our data which, if any, of these products lead to the respiratory chain inhibitions shown here. One possibility is mitochondrial dysfunction resulting from accumulation of calcium and phosphate as a consequence of Ca$^{2+}$ influx into the cytosol (34, 35). Several factors weigh against this type of mitochondrial damage in CM-injured L1210 cells: (a) Macrophage-induced injury is not abrogated in calcium-poor (26 µM) medium (Granger, D. L., unpublished results) as it is in cell injury induced by plasma membrane-directed agents (36). (b) The pattern of inhibition of mitochondrial functions upon Ca$^{2+}$ loading is different from CM-induced mitochondrial injury (34, 35, 37, 38). (c) Cellular Ca$^{2+}$ content of CM-injured L1210 cells is not increased (Granger, D. L., unpublished results) whereas this is a striking feature of ischemia/re-perfusion liver cell injury (39).

A more likely mechanism of pathogenesis may involve peroxidation of mitochondrial inner membrane phospholipids. Recently Narabayashi et al. (40) have characterized the sites of electron transport inhibition in heart submitochondrial particles subjected to NADH-dependent lipid peroxidation in the presence of ADP-Fe$^{3+}$. Under these conditions >90% of mitochondrial linoleic and arachidonic acids were converted to oxygenated products. The site most sensitive to inhibition was complex I, which lost >90% activity. Complex II activity was inhibited by ~80% but at a lower rate compared with complex I. Cytochrome c oxidase was inhibited to a minor degree (20%). In addition the activity of complex III (coenzyme Q-cytochrome c reductase) was inhibited by ~50%. These results are very similar to the pattern of inhibition present in CM-injured L1210 cells with the exception that in our system using permeabilized cells we have, as yet, been unable to assay complex III under conditions of maximal activity. Conceivably a moderate inhibition at this site could go undetected at the relatively low rate of electron transport limited by the activity of glycerophosphate dehydrogenase.

In another system enzymatic peroxidation of mitochondrial membrane lipids leads to similar effects on electron transport. During red blood cell maturation at the reticulocyte stage a cytosolic lipoxygenase appears that inhibits the mitochondrial respiratory chain when tested on heart submitochondrial particles (41). Again, complex I is most sensitive to inhibition, followed by complex II. Cytochrome c oxidase is inhibited to a minor degree and in this system electron flow from coenzyme Q to cytochrome c is not inhibited (41, 42). Presumably the reticulocyte lipoxygenase is involved in the involution of mitochondria that occurs during erythrocyte differentiation. This enzyme appears to be distinct from lipoxygenases of platelets, neutrophiles, and macrophages in that it oxygenates arachidonic acid at carbon 15 (43).

The foregoing examples raise the possibility that contact of L1210 cells with CM may lead to peroxidation of the unsaturated fatty acids of the inner mitochondrial membrane lipids. The resulting changes in membrane lipids might be expected to affect adversely the catalytic activities of complexes I and II of the respiratory chain. Prime candidates as mediators of lipid peroxidation are CM-generated oxygen intermediates (30, 44) although other possibilities exist.

The question as to whether CM-induced mitochondrial dysfunction is causally related to target cytostasis remains open. Inhibition of electron transport begins shortly before L1210 cell division stops (Fig. 4). At the time of target cell division arrest, oxidation of NAD-linked substrates in state 3 is inhibited by only ~25% It is possible, however, that this effect could upset the ATP/ADP ratio and/or the NADH/NAD ratio of injured L1210 cells. These alterations in turn could decrease the metabolic flux of substrates required for DNA polymerization, namely, the deoxyribonucleotides. Such an effect is commensurate with the findings of Krahenbuhl (4), which show complete abortion of S phase in synchronized target cells in contact with CM. However, at what level inhibition of DNA synthesis occurs is not known. The potential
relationship of the mitochondrial effects shown here and the cessation of cell division deserves further study. Measurements of the phosphorylation potential and the ratio of reduced:oxidized pyridine nucleotides during the early hours of CM-L1210 cell interaction are required.

We thank Dr. J. B. Hibbs, Jr. for his helpful suggestions and P. Ford and L. Loetell for preparing this manuscript.
